PREFACE.

THE VAST NUMBER of facts and observations, by which the recent progress of scientific and practical medicine has been marked, is diffusely recorded in the Transactions of learned societies, in journals, in monographs, and in systematic treatises. With progress so rapid, and information so diffused, it is extremely difficult alike for the practitioner, the teacher, and the student to keep pace. It was the perception of this difficulty which induced the Editor, when invited to undertake the production of a new Medical Dictionary, to engage in a task which, he was fully conscious, must be one of great labour and of great responsibility. He felt, however, that he would be rendering useful service to his Profession if he could bring together the latest and most complete information in a form which would allow of ready and easy reference. Accordingly, he invited the co-operation of certain of his colleagues and professional friends, both in this country and abroad; and evidence of the readiness with which this invitation has been accepted, is afforded by the list of contributors. Each contributor volunteered or was invited to write on a subject with which he was specially familiar. The present work, which is the result of these combined efforts, may therefore be regarded not only as a dictionary, but also as a treatise on systematic medicine, in which the articles on the more important subjects constitute monographs in themselves, whilst definitions and descriptions of matters having less claim to extended notice are given as fully as is required. Thus an endeavour has been made to supply, in a clear, condensed, and readily accessible form, all the information that is at present available for the use of the practitioner of medicine.

As indicated on the title-page, the work is primarily a dictionary of Medicine, in which the several diseases are fully discussed in alphabetical order. The description of each includes an account of its

ætiology and anatomical characters; its symptoms, course, duration, and terminations; its diagnosis, prognosis, and, lastly, its treatment. General Pathology comprehends articles on the origin, characters, and nature of disease, and the many considerations which these topics suggest. General Therapeutics will be found to include articles on the several classes of remedies—medicinal or otherwise—which are available for the purpose of treatment; on the modes of action of such remedies; and on the methods of their use. The articles devoted to the subject of Hygiene will be found to treat of the causes of disease, of its prevention, of the agencies and laws affecting public health, of the means of preserving the health of the individual, of the construction and management of hospitals, and of the nursing the sick. Lastly, the diseases peculiar to Women and Children are discussed under their respective headings, both in aggregate and in detail.

It may be well to explain that, although it has been found necessary to include some notice of diseases which fall more generally under the care of the surgeon, the work does not pretend to be a dictionary of Surgery; and also that, although certain drugs are enumerated in discussing subjects of general therapeutics, and of poisons and their actions, there has been no intention to invade the domain of *Materia Medica*.

It is right to observe that all the articles have been edited and revised with great care, so as to ensure a completeness and unity in the work, which it is not always possible to obtain in books composed by a number of writers.

The Editor desires also to state that, although the work has occupied several years in preparation, arrangements were made with the printers which have enabled him to revise every article which required revision, up to the time of going to press. Further, by the addition of an Appendix it has been possible to incorporate the latest contributions to medical knowledge.

Having thus set forth the aims and objects of his undertaking, and how far they have been carried out, the Editor has the great satisfaction of offering his thanks to his friends and colleagues, for the valuable assistance which he has received from them. He is fully conscious of the trouble which must often have been necessary in order

to condense extended knowledge of a familiar subject within the limited space which the nature of this work could afford.

The Editor has further the pleasing duty of offering his special thanks to DR. FREDERICK T. ROBERTS and to DR. J. MITCHELL BRUCE, who from the first have been his Assistant-editors and fellow-labourers. Without the help which they have afforded him, it would have been impossible for him to have fulfilled the duties which he undertook. He is well aware of the time and labour which their assistance has involved ; and he appreciates most fully the marked ability by which it has been characterised.

The Editor cannot conclude without a reference to some of those who were his friends and colleagues when this work was commenced, but who have since been taken away by death. He would specially mention the names of EDMUND PARKES, CHARLES MURCHISON, GEORGE CALLENDER, THOMAS BEVILL PEACOCK, JOHN ROSE CORMACK, LOCKHART CLARKE, TILBURY FOX, THOMAS HAYDEN, HARRY LEACH, ALEXANDER SILVER. The loss of these eminent men, many of them dear and valued friends, and all of them taken too soon from their unfinished labours, is to him a source of personal sorrow. The articles written by them for these pages were in most instances their last contributions to medical literature, and will be valued accordingly.

LONDON : *September* 1852.

LIST OF ILLUSTRATIONS.

FIG.	PAGE
1. <i>Odium albicans</i>	71
2. <i>Bilharzia haematobia</i> , male and female	107
3. <i>Bilharzia haematobia</i> , ovum of, with contained embryo and free sarcodogranules	107
4. Cardiogram	210
5. Renal casts—blood	213
6. " hyaline	213
7. " epithelial	213
8. " fatty	213
9. " granular	213
10. " enclosing crystals, and a smaller cast; also cast of seminal tubule with spermatozoa	213
11. <i>Filaria sanguinis-hominis</i>	252
12. Side view of the left hemisphere of the monkey, illustrating localisation of the cerebral centres	297
13. Side view of the left hemisphere of man, illustrating localisation of the cerebral centres	297
14. <i>Cysticercus (tae) cellulosus</i> , removed from the human eye	323
15. <i>Cysticercus</i> in a portion of measles pork	323
16. <i>Distoma conjunctum</i>	401
17. <i>Dracunculus medinensis</i>	403
18. <i>Filaria sanguinis-hominis</i> , anterior end of the mature	512
19. <i>Filaria sanguinis-hominis</i> , a portion of the mature, showing uterine tubules, &c.	512
20. <i>Filaria sanguinis-hominis</i> , ova and embryos of	513
21. Fungoid filaments and capsules from fungus disease of India	522
22. Fatty degeneration of the heart	594
23. Fatty growth in the substance of the heart	597
24. Hydatids of four weeks' growth, showing ectocyst and endocyst	654
25. Group of Echinococci, with their hook-crowns inverted	654
26. The so-called 'Echinococcus head,' showing hooks, suckers, cilia, and corpuscles	654

FIG	PAGE
27. Micrococci, different forms of	974
28. Red blood-corpuscles—human	982
29. Scaly epithelial cells	982
30. Leucocytes; pus, mucous, or white blood-corpuscles	982
31. Ciliated epithelial cells	982
32. Cotton fibres, showing characteristic twist	982
33. Milk, showing colostrum corpuscles and oil-globules	982
34. Particles of vomited matter	982
35. Epithelium from urinary tracts	982
36. Spermatozoa—human	982
37. Fragments of hair	982
38. <i>Sarcina ventriculi</i>	982
39. Hooklets of echinococcus	982
40. From phthisical sputum, showing elastic fibres of lung-tissue and leucocytes	982
41. Haemin crystals from old blood-clot	982
42. Cubes of chloride of sodium	982
43. Leucin	982
44. Tyrosin	982
45. Uric acid, various forms	982
46. Cholesterol plates	982
47. Cystin	982
48. Oxalate of lime: dumb-bells and octahedra	982
49. Triple phosphate of ammonia and magnesia	982
50. <i>Torula cerevisiae</i> : yeast fungus	982
51. Sputum of early pneumonia, showing red blood corpuscles and leucocytes	982
52. Shreds of elastic tissue in sputum of phthisis	982
53. <i>Odium albicans</i> ; thrush.	982
54. <i>Penicillium glaucum</i>	982
55. Pulver-trace—typical	1295
56. of high tension	1295

LIST OF ILLUSTRATIONS.

FIG.	PAGE	FIG.	PAGE
57. Pulse-trace—of low tension . . .	1295	92. <i>Tænia medicea</i> — <i>Slata</i> , proglottis of . . .	1585

LIST OF CONTRIBUTORS.

- ADAMS, WILLIAM**, Surgeon to the Great Northern Hospital.
- AITKEN, WILLIAM, M.D., F.R.S.**, Professor of Pathology in the Army Medical School Netley.
- ALLBUTT, T. CLIFFORD, M.A., M.D., F.R.S.**, Senior Physician to the Leeds General Infirmary, and Lecturer on Practice of Physic, Leeds School of Medicine.
- ALLCHIN, W. H., M.B., F.R.S.E.**, Physician to, and Lecturer on Physiology and Pathology at, the Westminster Hospital; Physician to the Victoria Hospital for Children.
- ANDREW, JAMES, M.D.**, Physician to, and Joint Lecturer on Physic at, St. Bartholomew's Hospital; Consulting Physician to the City of London Hospital for Diseases of the Chest.
- BALFOUR, GEORGE W., M.D., F.R.S.E.**, Physician to the Royal Infirmary, and Consulting Physician to the Royal Hospital for Children, Edinburgh.
- BANHAM, G. A.**, late Veterinary Assistant at the Brown Institution.
- BARNES, ROBERT, M.D.**, Obstetric Physician to, and Lecturer on Midwifery and Diseases of Women at, St. George's Hospital, Consulting Physician to the Royal Maternity Charity.
- BASTIAN, H. CHARLTON, M.A., M.D., F.R.S.**, Physician to, and Professor of Clinical Medicine at, University College Hospital, Professor of Pathological Anatomy, University College; and Physician to the National Hospital for the Paralysed and Epileptic.
- BAUMLER, C. G. H., M.D.**, Professor of Clinical Medicine, and Director of the Medical Clinic, University of Freiburg in Baden.
- BECK, MARCUS, M.B., M.S.**, Assistant Surgeon to, and Assistant Professor of Clinical Surgery at, University College Hospital.
- BEDDOE, JOHN, B.A., M.D., F.R.S.**, late Physician to the Bristol Royal Infirmary.
- BELLAMY, EDWARD**, Surgeon to, and Lecturer on Anatomy at, the Charing Cross Hospital.
- BENNET, J. HENRY, M.D.**, late Physician-Accoucheur, Royal Free Hospital.
- BENNETT, SIR J. RISDON, M.D., LL.D., F.R.S.**, late President of the Royal College of Physicians, Consulting Physician to St. Thomas's Hospital, and to the City of London Hospital for Diseases of the Chest.
- BEVERIDGE, ROBERT, M.B.**, Physician to, and Lecturer on Clinical Medicine at, the Aberdeen Royal Infirmary.

- BINZ, CARL, M.D.**, Professor of Pharmacology in the University of Bonn.
- BIRKETT, JOHN**, Consulting Surgeon to Guy's Hospital.
- BISHOP, JOHN, M.D., C.M.**, Assistant Surgeon to the Royal Infirmary, Edinburgh.
- BLANDFORD, G. F., M.D.**, Lecturer on Psychological Medicine at St. George's Hospital.
- BOWLES, R. L., M.D.**, Physician to St. Andrew's Convalescent Hospital, Folkestone.
- BRISTOWE, J. SYER, M.D., F.R.S.**, Physician to, and Joint Lecturer on Medicine at, St. Thomas's Hospital.
- BROADBENT, W. H., M.D.**, Physician to, and Lecturer on Medicine at, St. Mary's Hospital; Consulting Physician to the London Fever Hospital.
- BROWN-SÉQUARD, C. E., M.D., LL.D., F.R.S.**, Professor of Medicine, Collège de France.
- BRUCE, J. MITCHELL, M.A., M.D.**, Physician to, and Lecturer on Materia Medica and Therapeutics at, the Charing Cross Hospital, Assistant Physician to the Hospital for Consumption and Diseases of the Chest, Brompton.
- BRUCE, WILLIAM, M.A., M.D.**, Physician to the Ross Memorial Hospital, Dingwall.
- BRUNTON, T. LAUDER, M.D., D.Sc., F.R.S.**, Assistant Physician to, and Lecturer on Materia Medica and Therapeutics at, St. Bartholomew's Hospital.
- BUCHANAN, GEORGE, B.A., M.D., F.R.S.**, Medical Officer, H.M. Local Government Board; Consulting Physician to the London Fever Hospital.
- BUTLIN, H. T.**, Assistant Surgeon to, and Demonstrator of Surgery at, St. Bartholomew's Hospital; Surgeon to the Metropolitan Free Hospital.
- BUZZARD, THOMAS, M.D.**, Physician to the National Hospital for the Paralysed and Epileptic.
- CADGE, WILLIAM**, Surgeon to the Norfolk and Norwich Hospital.
- CALLENDER, The late G. W., F.R.S.**, Surgeon to, and Lecturer on Surgery at, St. Bartholomew's Hospital.
- CANTLIE, JAMES, M.A., M.B., C.M.**, Senior Assistant Surgeon to, and Demonstrator of Anatomy at, the Charing Cross Hospital.
- CARPENTER, W. B., C.B., M.D., LL.D., F.R.S.**
- CARTER, R. BRUDENELL**, Ophthalmic Surgeon to, and Lecturer on Ophthalmic Surgery at, St. George's Hospital.
- CAYLEY, WILLIAM, M.D.**, Physician to, and Lecturer on Medicine at, the Middlesex Hospital; Physician to the London Fever Hospital.
- CLARKE, The late J. LOCKHART, M.D., F.R.S.**, Physician to the Hospital for Diseases of the Nervous System.
- CLARKE, W. FAIRLIE, M.A., M.D.**, late Assistant Surgeon to the Charing Cross Hospital.
- CLOVER, The late J. T.**, Lecturer on Anæsthetics at University College Hospital.
- COBBOLD, CHARLES S. W., M.D.**, Senior Assistant Medical Officer, Colney Hatch Asylum.
- COBBOLD, T. SPENCER, M.D., F.R.S.**, Professor of Botany and Helminthology at the Royal Veterinary College.

- COLLIE, ALEXANDER, M.D.**, Medical Officer, Fever Hospital, Homerton.
- COOPER, ARTHUR, M.R.C.S.**, late House Surgeon to the Male Lock Hospital.
- CORMACK, The late SIR JOHN ROSE, K.B., M.D., F.R.S.E.**, Physician to the Hertford British Hospital, Paris.
- CUNNINGHAM, D. DOUGLAS, M.D.**, Surgeon-Major H.M. Bengal Army.
- CURLING, T. B., F.R.S.**, Consulting Surgeon to the London Hospital.
- CURNOW, JOHN, M.D.**, Assistant Physician to King's College Hospital; Professor of Anatomy at King's College, Senior Visiting Physician to the Seamen's Hospital.
- DALBY, W. B., B.A., M.B.**, Aural Surgeon to, and Lecturer on Aural Surgery at, St. George's Hospital.
- DAVIDSON, ALEXANDER, M.A., M.D.**, Physician to the Royal Infirmary, Liverpool, and Lecturer on Pathology at the Liverpool Medical School.
- DE ZOUICHE, ISAAH, M.D.**, Honorary Physician to the Dunedin Hospital, New Zealand.
- DOWN, J. LANGDON, M.D.**, Physician to, and Lecturer on Clinical Medicine at, the London Hospital.
- DUNCAN, J. MATTHEWS, M.A., M.D., LL.D., F.R.S.E.**, Physician-Accoucheur to, and Lecturer on Midwifery at, St. Bartholomew's Hospital.
- DURHAM, ARTHUR E.**, Surgeon to, and Lecturer on Surgery at, Guy's Hospital.
- ECHEVERRIA, M. G., M.D.**, late Physician-in-Chief to the Hospital for Epileptics and Paralytics, and to the City Asylum for the Insane, New York.
- EWART, JOSEPH, M.D.**, Retired Deputy Surgeon-General, H.M. Bengal Army; late Professor of Medicine, Principal, and Senior Physician, Czechia Medical College.
- EWART, WILLIAM, B.A., M.D.**, Assistant Physician to St. George's Hospital, late Assistant Physician and Pathologist to the Hospital for Consumption and Diseases of the Chest, Brompton.
- FARQUHARSON, ROBERT, M.D., M.P.**, late Physician to the Belgrave Hospital for Children, and late Assistant Physician to, and Lecturer on Materia Medica at, St. Mary's Hospital.
- FAYRER, SIR JOSEPH, K.C.S.I., M.D., LL.D., F.R.S.**, Honorary Physician to H.M. the Queen, and to H.R.H. the Prince of Wales; President of the Medical Board, India Office, Consulting Physician to the Charing Cross Hospital.
- FENWICK, SAMUEL, M.D.**, Physician to, and late Lecturer on Medicine at, the London Hospital, Assistant Physician to the City of London Hospital for Diseases of the Chest.
- FERRIER, DAVID, M.A., M.D., LL.D., F.R.S.**, Assistant Physician to King's College Hospital, Professor of Forensic Medicine at King's College, Physician to the National Hospital for the Paralysed and Epileptic.
- FINNEY, J. M., B.A., M.D.**, Physician to the City of Dublin Hospital; King's Professor of the Practice of Medicine at the School of Physic in Ireland, and Professor of Clinical Medicine in Sir Patrick Dun's Hospital.
- FOSTER, BALTHAZAR W., M.D.**, Physician to the General Hospital, and Professor of the Principles and Practice of Physic at Queen's College, Birmingham.
- FOX, E. LONG, M.D.**, Consulting Physician to the Bristol Royal Infirmary, and late Lecturer on the Principles and Practice of Medicine at the Bristol School of Medicine.

FOX, T. COLCOTT, B.A., M.B., Physician to the St. George's and St. James's Dispensary ; Assistant Physician to the Victoria Hospital for Children.

FOX, The late TILBURY, M.D., Physician to the Skin Department, University College Hospital.

GALTON, CAPTAIN DOUGLAS, R.E. (retired), C.B., D.C.L., F.R.S.

GASCOYEN, The late GEORGE G., Surgeon to the Lock Hospital ; and Assistant Surgeon to, and Lecturer on Surgery at, St. Mary's Hospital.

GEE, SAMUEL, M.D., Physician to St. Bartholomew's Hospital, and to the Hospital for Sick Children ; Joint-Lecturer on Practice of Physic at St. Bartholomew's Hospital.

GODLEE, RICKMAN J., B.A., M.B., M.S., Assistant Surgeon to University College Hospital ; Demonstrator of Anatomy at University College, Assistant Surgeon to the North-East Hospital for Children.

GODSON, CLEMENT, M.D., Consulting Physician to the City of London Lying-in Hospital, Assistant Physician-Accoucheur to St. Bartholomew's Hospital.

GOWERS, W. R., M.D., Assistant Physician to, and Assistant Professor of Clinical Medicine at, University College Hospital, Physician to the National Hospital for the Paralysed and Epileptic.

GREEN, T. HENRY, M.D., Physician to, and Lecturer on Pathology at, the Charing Cross Hospital ; Assistant Physician to the Hospital for Consumption and Diseases of the Chest, Brompton.

GREENFIELD, W. S., M.D., Professor of General Pathology and Clinical Medicine in the University of Edinburgh.

GRIMSHAW, T. W., M.A., M.D., Registrar-General for Ireland ; Consulting Physician to the Fever Hospital, and to Steeven's Hospital, Dublin.

HAWARD, J. WARRINGTON, Surgeon to St. George's Hospital, late Assistant Surgeon to the Hospital for Sick Children.

HAYDEN, The late THOMAS, Physician to the Mater Misericordiarum Hospital, Dublin ; Professor of Anatomy and Physiology, Catholic University, Dublin.

HERMAN, G. ERNEST, M.B., Assistant Obstetric Physician to the London Hospital ; Physician to the Royal Maternity Charity.

HICKS, J. BRAXTON, M.D., F.R.S., Physician-Accoucheur to, and Lecturer on Midwifery and Diseases of Women and Children at, Guy's Hospital.

HILL, BERKELEY, M.B., Surgeon to, and Professor of Clinical Surgery at, University College Hospital ; Teacher of Practical Surgery at University College, Surgeon to the Lock Hospital.

HOLMES, TIMOTHY, M.A., Surgeon to, and Lecturer on Surgery at, St. George's Hospital.

HORSLEY, V. A. H., B.S., M.B., Assistant to the Professor of Pathological Anatomy, University College ; Surgical Registrar, University College Hospital.

HOWARD, BENJAMIN, M.D., late Professor of Medicine, and Lecturer on Medicine, in the University of New York.

HUTCHINSON, JONATHAN, F.R.S., Senior Surgeon to the London Hospital, and to the Hospital for Diseases of the Skin ; Consulting Surgeon to the Royal London Ophthalmic Hospital.

IRVINE, The late J. PEARSON, B.A., B.Sc., M.D., Assistant Physician to, and Lecturer on Forensic Medicine at, the Charing Cross Hospital; Physician to the Victoria Hospital for Children.

JENNER, SIR WILLIAM, Bart., K.C.B., M.D., D.C.L., LL.D., F.R.S., Physician-in-Ordinary to H.M. the Queen, and to H.R.H. the Prince of Wales; President of the Royal College of Physicians, Consulting Physician to University College Hospital.

JONES, JOSEPH, M.D., President Board of Health, State of Louisiana, New Orleans.

LATHAM, P. W., A.M., M.D., Physician to Addenbrooke's Hospital; Downing Professor of Medicine in the University of Cambridge.

LEACH, The late HARRY, Medical Officer of Health for the Port of London, and Physician to the Seamen's Hospital, Greenwich.

LEGG, J. WICKHAM, M.D., Assistant Physician to, and Lecturer on Pathological Anatomy at, St. Bartholomew's Hospital.

LEWIS, TIMOTHY, M.D., Surgeon-Major, H.M. Army.

LITTLE, JAMES, M.D., Physician to the Adelaide Hospital, Dublin; Professor of Practice of Physic in the Royal College of Surgeons in Ireland, Consulting Physician to the Rotunda Lying-in Hospital.

LIVING, ROBERT, M.A., M.D., Physician for Diseases of the Skin to, and Lecturer on Diseases of the Skin at, the Middlesex Hospital.

MCCARTHY, JEREMIAH, M.A., M.B., Surgeon to, and Lecturer on Physiology at, the London Hospital.

MACCORMAC, SIR WILLIAM, M.A., M.Ch., Surgeon to, and Lecturer on Surgery at, St. Thomas's Hospital.

McKENDRICK, J. GRAY, M.D., F.R.S.E., Professor of the Institutes of Medicine in the University of Glasgow.

MACKENZIE, STEPHEN, M.D., Physician to, and Lecturer on the Principles and Practice of Medicine at, the London Hospital.

MACLEAN, W. C., C.B., M.D., Inspector-General of Hospitals, Professor of Military Medicine in the Army Medical School, Netley.

MACNAMARA, CHARLES, Surgeon to the Westminster Hospital, and to the Westminster Ophthalmic Hospital, Joint-Lecturer on Surgery at the Westminster Hospital.

MACPHERSON, JOHN, M.A., M.D., Inspector-General of Hospitals, H.M. Bengal Army (retired), Physician to the Scottish Hospital.

MADDEN, T. MORE, Obstetric Physician to the Mater Misericordiarum Hospital, Dublin.

MANSON, PATRICK, M.D., Army.

MEREDITH, W. A., M.B., C.M., Surgeon to the Samaritan Free Hospital for Women and Children.

MERYON, The late EDWARD, M.D., Physician to the Hospital for Epilepsy and Paralysis.

MUIRHEAD, CLAUD, M.D., Physician to, and Lecturer on Clinical Medicine at, the Royal Infirmary, Edinburgh.

MURCHISON, The late CHARLES, M.D., LL.D., F.R.S., Physician to, and Special Professor of Clinical Medicine at, St. Thomas's Hospital, Consulting Physician to the London Fever Hospital.

MYERS, A. B. R., Surgeon, Coldstream Guards.

NETTLESHIP, EDWARD. Ophthalmic Surgeon to St. Thomas's Hospital, and to the Hospital for Sick Children; Lecturer on Ophthalmic Surgery at St. Thomas's Hospital.

NIGHTINGALE, FLORENCE.

OLIVER, GEORGE, M.D., Harrogate.

ORD, W. M., M.D., Physician to, and Lecturer on Medicine at, St. Thomas's Hospital.

PAGET, SIR JAMES, Bart. D.C.L., LL.D., F.R.S., Sergeant-Surgeon to H.M. the Queen; Surgeon to H.R.H. the Prince of Wales, Consulting Surgeon to St. Bartholomew's Hospital.

PARKES, The late EDMUND A., M.D., F.R.S., Professor of Hygiene in the Army Medical School, Netley.

PAVY, F. W., M.D., F.R.S., Physician to, and Lecturer on Medicine at, Guy's Hospital.

RAYNE, J. FRANK, B.A., B.Sc., M.D., Senior Assistant Physician to, and Lecturer on General Pathology at, St. Thomas's Hospital.

PEACOCK, The late T. BEVILL, M.D., Honorary Consulting Physician to St. Thomas's Hospital; and Consulting Physician to the City of London Hospital for Diseases of the Chest.

PLAYFAIR, W. S., M.D., Physician-Accoucheur to H.I. and R.H. the Duchess of Edinburgh, Physician for Diseases of Women and Children to King's College Hospital, and Consulting Physician to the General Lying-in Hospital, Professor of Obstetric Medicine at King's College.

POORE, G. VIVIAN, M.D., Assistant Physician to University College Hospital; Professor of Medical Jurisprudence, University College.

POWELL, R. DOUGLAS, M.D., Physician to the Middlesex Hospital, and to the Hospital for Consumption and Diseases of the Chest, Brompton.

QUAIN, RICHARD, M.D., F.R.S., Consulting Physician to the Hospital for Consumption and Diseases of the Chest, Brompton.

RAIDCLIFFE, J. NITTELN, Assistant Medical Officer, Local Government Board.

REDWOOD, THEOPHILUS, Ph.D., Professor of Chemistry and Pharmacy, Pharmaceutical Society of Great Britain.

ROBERTS, FREDERICK T., M.D., B.Sc., Physician to, and Professor of Clinical Medicine at, University College Hospital, Professor of Maternal Medicine at University College, Physician to the Hospital for Consumption and Diseases of the Chest, Brompton.

ROBERTS, WILLIAM, B.A., M.D., F.R.S., Physician to the Manchester Royal Infirmary, Professor of Clinical Medicine, Owens College School of Medicine.

ROSE, WILLIAM, B.S., M.B., Assistant Surgeon to King's College Hospital, Surgeon to the Royal Free Hospital.

ROY, C. S., M.D., Professor Superintendent of the Brown Institution, London.

RUSSELL, JAMES A., M.A., M.B., C.M., Inspector of Anatomy for Scotland, Lecturer on Sanitation, Watt's Institution, Edinburgh.

SALTER, S. J., M.B., F.R.S., F.I.S., Late Dental Surgeon to Guy's Hospital.

SANGSTER, ALFRED, B.A., M.B., Physician for Diseases of the Skin to, and Lecturer on Skin Diseases at, the Charing Cross Hospital.

- SAUNDERS, R. M.D.**, Assistant Physician to the General Hospital, Birmingham.
- SEATON**, The late **EDWARD C. M.D.**, Medical Officer, Local Government Board.
- SHAFTER, THOMAS, M.D., LL.D.**, Consulting Physician to the Devon and Exeter Hospital.
- SIBBALD, JOHN, M.D., F.R.S.E.**, Commissioner in Lunacy for Scotland.
- SILVER**, The late **ALEXANDER, M.A., M.D.**, Physician to, and Lecturer on Physiology at, the Charing Cross Hospital.
- SIMON, JOHN, C.B., D.C.L., LL.D., F.R.S.**, Consulting Surgeon to St. Thomas's Hospital; late Medical Officer to Her Majesty's Privy Council, and to the Local Government Board.
- SIMPSON, ALEXANDER R., M.D.**, Physician to the University Clinical Ward for Diseases of Women, Royal Infirmary, Edinburgh; Professor of Midwifery and Diseases of Women and Children in the University of Edinburgh.
- SMITH, EUSTACE, M.D.**, Physician to H.M. the King of the Belgians; Physician to the City of London Hospital for Diseases of the Chest, and to the East London Hospital for Children.
- SMITH, W. JOHNSON**, Surgeon to the Seamen's Hospital, Greenwich.
- SOUTHEY REGINALD, M.D.**, Physician to, and Lecturer on Forensic Medicine and Hygiene at, St. Bartholomew's Hospital.
- SPARKS**, The late **EDWARD I., M.A., M.B.**, Physician for Diseases of the Skin to the Charing Cross Hospital, and Physician to the Royal Infirmary for Women and Children.
- SQUIRE, WILLIAM, M.D.**, Physician to the North London Hospital for Diseases of the Chest, and to St. George's Dispensary.
- STEVENSON, THOMAS, M.D.**, Lecturer on Chemistry and Medical Jurisprudence at Guy's Hospital, Analyst to St. Francis &c.
- STEWART, T. GRAINGER, M.D., F.R.S.L.**, Ordinary Physician to H.M. the Queen in Scotland, Professor of Practice of Physic in the University of Edinburgh.
- STREATFIELD, J. F.**, Surgeon to the Royal London Ophthalmic Hospital, Professor of Clinical Ophthalmic Surgery at, and Ophthalmic Surgeon to, University College Hospital.
- THIN, GEORGE, M.D.**, London.
- THOMPSON, L. SYMES, M.D.**, Physician to the Hospital for Consumption and Diseases of the Chest, Brompton.
- THOMPSON, SIR HENRY**, Surgeon Extraordinary to H.M. the King of the Belgians, Consulting Surgeon to University College Hospital, Laureate Professor of Clinical Surgery at University College.
- THORNTON, W. PUGIN**, Surgeon to the St. Marylebone General Dispensary.
- THOROWGOOD, J. C., M.D.**, Physician to the City of London Hospital for Diseases of the Chest, and to the West London Hospital, Lecturer on Materia Medica at the Middlesex Hospital.
- TOKE, J. BATTY, M.D., F.R.S.E.**, formerly Lecturer on Mental Diseases at the Royal College of Surgeons, Edinburgh.
- WALKER, T. J., M.D.**, Surgeon to the Peterborough Infirmary and Dispensary.

WARD, The late STEPHEN H., M.D. Consulting Physician to the Seamen's Hospital, Greenwich; and Physician to the City of London Hospital for Diseases of the Chest.

WARDELL, J. R., M.D., Consulting Physician to the Tunbridge Wells Infirmary.

WATTS, A. T. H., M.D., Physician to the Royal Infirmary, Liverpool; Lecturer on Principles and Practice of Medicine at the Liverpool School of Medicine.

WEBER, HERMANN, M.D., Physician to the German Hospital.

WELLS, T. SPENCER, President of the Royal College of Surgeons; Surgeon to the Queen's Household; Consulting Surgeon to the Samaritan Hospital for Women and Children.

WILLIAMS, C. THEODORE, M.A., M.D., Physician to the Hospital for Consumption and Diseases of the Chest, Brompton.

WILSON, SIR ERASMUS, LL.D., F.R.S., late President of the Royal College of Surgeons, Professor of Dermatology, Royal College of Surgeons.

WILTSHIRE, ALFRED, M.D., Physician-Accoucheur to, and Joint Lecturer on Obstetric Medicine at, St. Mary's Hospital; Physician for Diseases of Women to the West London Hospital.

WOOD, JOHN, F.R.S., Surgeon to King's College Hospital, and Professor of Clinical Surgery at King's College.

DICTIONARY OF MEDICINE.

A

ABDOMEN, Diseases of the.— Before entering upon the study of the particular diseases which are liable to be met with in connexion with each of the principal regions of the body it is expedient to regard them from a general point of view, as such a course helps materially in clearing the way for their clinical investigation. This general survey is particularly advantageous in the case of abdominal diseases, which are necessarily very numerous and varied, both as regards the structure affected and the nature of the morbid change they present; they are consequently difficult to recognise with certainty in many instances, and are occasionally involved in much obscurity.

Excluding a few peculiar affections, the diseases of the abdomen may be arranged under the following groups:—

I. Diseases of the anterior abdominal walls.

II. Diseases of the peritoneum and its folds.

III. Diseases of the organs contained within the abdominal cavity, namely:— 1. Stomach and Intestines; 2. Hepatic organs, including the liver, gall-bladder, and gall-ducts; 3. Spleen; 4. Pancreas; 5. Supra-renal capsules; 6. Urinary apparatus, viz., the kidneys and their ducts, and the bladder; 7. Female Generative organs, including the uterus and its broad ligament, the Fallopian tubes, and the ovaries; 8. Absorbent glands.

IV. Diseases of the abdominal vessels, especially the aorta and the iliac arteries.

V. Diseases of the sympathetic or other nerves contained within the abdomen.

VI. Diseases originating in connexion with the cellular tissue, such as inflammation or abscess.

VII. Diseases springing from the posterior boundary of the abdomen; from the pelvis or the structures lining it; or from the diaphragm, and invading the abdominal cavity.

VIII. Diseases encroaching upon the abdomen from other parts, especially from the thorax.

It must be borne in mind that the groups of diseases above-mentioned may be presented in various combinations, two or more structures being not uncommonly implicated at the same time.

The special nature and mode of origin of the diseases thus summarised will be discussed under

their appropriate headings, but a few general observations on this subject may prove serviceable. Several of the abdominal organs are very liable to so-called *functional disorders*, being much exposed to the repeated action of various disturbing influences, and these disorders often give rise to prominent and troublesome symptoms, which are urgently complained of by the patient. Definite *organic diseases* are also of common occurrence, many of them being of a very serious character. Some of the organs contained within the abdomen are subject to *disposition or displacement*, as well as to *malformations*, these being either congenital or acquired, while the hollow viscera may be the seat of *obstruction or accumulations* of different kinds, and each of these conditions may become clinically important.

Abdominal lesions are frequently purely *local* in their origin, but several of them are but local manifestations of some general condition, being either associated with certain acute febrile diseases, e.g., typhoid fever; or with some constitutional cachexia, such as cancer. Again, symptoms connected with the abdomen may depend upon disease in some remote part of the body, or some of its organs may become the seat of morbid changes as a consequence of disease in other structures. For instance, vomiting is frequently associated with cerebral disorders, while affections of the heart are liable to lead to troublesome symptoms, as well as to serious lesions in connexion with many of the abdominal viscera. Lastly, a morbid condition of one organ within the abdomen may be the direct means of originating *secondary mischief* in other structures.

CLINICAL INVESTIGATION.— The clinical examination of cases in which the symptoms point to the abdomen as the seat of mischief should always be conducted with particular care and thoroughness, as well as in a systematic manner, otherwise serious mistakes are liable to be made. It is also very desirable to avoid forming any definite conclusion as to the nature of the complaint hastily or on insufficient data, but rather to wait and observe the course of events in any doubtful case, repeating the investigation from time to

time, when any obscurity which may exist will often be cleared away. The past and family history of the patient, with the course and progress of the symptoms, are often of material assistance in diagnosis, and demand due attention in every instance. The chief clinical phenomena which may be associated with abdominal affections, and with reference to which it is requisite to inquire, may be thus indicated. First, there are usually symptoms directly connected with the structure implicated, such as pain and other morbid sensations, disorders of secretory or other functions, or excited action. Secondly, several of the organs mutually affect each other, either from being anatomically or physiologically related, or from a morbid condition of one part causing pressure upon or irritation of some neighbouring structure. In this way numerous symptoms are liable to arise, sometimes in remote parts, and often of material significance. Thirdly, sympathetic or reflex phenomena in connexion with organs in other regions of the body are frequently excited by many abdominal disorders, such as palpitation of the heart, convulsions, and other nervous disturbances. Fourthly, the general system often suffers seriously, and in various ways. For instance, pyrexia may be excited; the blood may become impoverished or impregnated with noxious materials; or more or less general wasting and debility may be induced. Where an abdominal disease is but a local manifestation of some constitutional condition, it commonly aggravates materially the general symptoms, while in connexion with lesions of certain of the abdominal viscera these general symptoms constitute in many cases the most prominent clinical features. Fifthly, morbid conditions within the abdomen not unfrequently interfere directly with the diaphragm and the thoracic organs, occasionally also they invade upon the chest, or actually make their way into this cavity through the diaphragm. In rare instances morbid products, such as pus, may find their way to distant parts of the body. In these different ways a variety of symptoms may be caused, sometimes of a curious nature and difficult to explain. Lastly, abdominal diseases are frequently attended with abnormal physical or objective signs, which are revealed on physical examination, and these are of such importance that they demand separate consideration.

PHYSICAL EXAMINATION.—The neglect of submitting patients to a satisfactory physical examination is a frequent source of error in diagnosis in cases of abdominal disease, and there ought to be no hesitation or delay in resorting to this method of clinical investigation whenever it seems called for. The precise course to be pursued must vary according to circumstances, but the following outline will serve to indicate the plan of procedure ordinarily required.

First, there are certain modes of examination which are applied to the abdomen externally, including *Inspection*; *Palpation* or *Manspulation*; *Measurement* or *Measurement*; *Percussion*; and *Auscultation* (see **PHYSICAL EXAMINATION**). Of these, inspection, palpation, and percussion are by far the most important, and have, in the large majority of cases, to be relied upon for the information required. In ex-

ceptional instances *Succession* or shaking the patient proves serviceable, by bringing out certain sensations or sounds. In order to carry out these methods properly, it is necessary to expose the abdomen sufficiently, due regard being paid to decency in the examination of females; to place the patient in a suitable position; and to see that the muscles of the abdominal walls are duly relaxed. The best position usually is for the patient to lie on the back, in a half-reclining attitude, with the head and shoulders well raised, and the thighs and knees more or less flexed. This posture serves to relax the abdominal muscles, which may be further aided by taking off the patient's attention by conversation or in other ways, as well as by directing him to breathe deeply. The position, however, has often to be varied in the investigation of particular cases, and much information is frequently gained by noticing the effects of altering the posture.

The objective conditions which may be revealed by the modes of examination thus far considered are as follows:—1. The state of the superficial structures. 2. The size and shape of the abdomen, generally and locally, as indicating an alteration in the volume of the ordinary contents of the abdomen, or the presence of some new or fresh element, such as dropsical fluid or a tumour. 3. The characters of the abdominal respiratory movements, and the presence of any unusual sensations during the act of breathing, such as friction-fremitus. 4. The sensations experienced on palpation and percussion over the abdomen, either as a whole, or in any particular part of it, such as its mobility, degree of resistance, regularity, consistence, &c., as well as the presence of certain peculiar sensations, *e.g.*, fluctuation, or hydatid-fremitus. 5. The presence and characters of any pulsation. 6. The occurrence of abnormal movements within the abdomen, as those of a fetus. 7. The sounds elicited, generally and locally, on percussion. 8. The presence of certain sounds within the abdomen, heard on auscultation, such as friction-sounds, murmurs connected with aneurism or due to pressure on an artery; or murmurs and sounds associated with the pregnant uterus.

Secondly, it not uncommonly happens that special modes of examination have to be applied to particular organs within the abdomen, in order to arrive at a diagnosis with any certainty. And here it may be remarked that it is highly important in all cases to see that no accumulation of feces exists within the bowels, and that the bladder is properly emptied, otherwise very serious mistakes are liable to be made. Purgatives and enemata are needed in order to remove any fecal collection. The urine should also be properly tested in every instance; and much information may often be gained in the investigation of affections of the alimentary canal, from a personal inspection or more complete examination of feces or vomited matters. The abdominal organs to which special modes of examination are chiefly applicable are the female generative organs, which are investigated per vaginam (see **WOMEN, Diseases of**); the bladder, by means of the catheter, the sound, and other

surgical instruments; the stomach, by the use of the stomach-pump, probang, &c.; and the intestines, by examining with the finger, hand, or surgical instruments per rectum, or by injecting water or air through the anus into the bowels. The ordinary modes of examination already mentioned may afford assistance when employed along with some of the special methods just indicated.

Thirdly, occasionally it is requisite to have recourse to exceptional modes of investigation, such as the use of the exploring trochar or aspirator, or to the administration of chloroform. The latter may afford direct information in certain abdominal conditions, and it may also materially assist in carrying out other methods of exploration.

The abnormal conditions discoverable by physical examination may involve the entire abdomen, giving rise, for instance, to general enlargement or retraction, or they may be limited to some particular region, e.g., enlarged organs, tumours, or abscesses. This part of the body has been artificially divided by anatomists into regions, and the seat of any local morbid condition can thus be defined and described. The diseases peculiar to the several regions will be considered under their respective headings.

FRANKRICK T. ROBERTS.

ABDOMINAL ANEURISM includes aneurism of the aorta, and of any of its branches within the abdomen.

Aneurism of the Abdominal Aorta is essentially a disease of middle age. Of fifty-nine cases collected by Dr. Crisp, thirty-three were under the age of forty. It is more common in the male than in the female sex in the proportion of about 8 : 1, and is usually traceable to strain, or to a blow upon the abdomen or back. The aneurism is most frequently located in that portion of the vessel included between the aortic opening in the diaphragm and the origin of the superior mesenteric artery. In this situation the tumour is deeply seated, liable to tension from the crura of the diaphragm, and likely to involve the great splanchnic nerves, the semilunar ganglia, and the solar plexus. Hence the occasional difficulty of diagnosis, and the frequency of boring pain in the back from erosion of the vertebrae, and of paroxysms of radiating pain in the abdominal viscera from stretching of the adjacent nerves. When situated lower down in the course of the aorta, the disease is less obscure, and the symptoms are less urgent. Aneurism of the abdominal aorta is usually of the *falx* variety, and, as contrasted with thoracic aneurism, it is less often associated with extensive atheroma of the aorta, and with fatty or other structural disease of the heart. The symptoms referable to eccentric pressure are also fewer, and, with the exception of pain, are less urgent.

SYMPTOMS AND SIGNS.—Of the symptoms, *pain* is the most characteristic and the most urgent; it is of two kinds, which are not, however, necessarily associated. In its usual form the pain of abdominal aneurism is essentially neuralgic; it is intermittent and paroxysmal,—radiating through the abdomen, back, pelvis, and base of the thorax, and not unfrequently into either groin or testicle. The recession is sudden, and usually attributable

to some definite cause of vascular enervation. The duration extends over a period varying from one to three hours, rarely longer; and the cessation is equally abrupt, leaving the patient in a state of exhaustion, but quite free from actual suffering. The second kind of pain referred to is continuous and boring; fixed at a particular point of the vertebral column; aggravated by pressure at this point, by active movement or stamping, and by gently turning the patient half round upon his axis in the standing posture, but relieved by anti-recumbency or leaning forward. Pain so characterised is pathognomonic of erosion of the vertebrae. Pressure of an aneurism may affect the functions of several organs within the abdomen. Thus *jaundice* may result from pressure upon the hepatic or common biliary duct; it is, however, more frequently due to an aneurism of the hepatic or of the superior mesenteric artery. *Interference with the urinary secretion*, and the consequences thereof, from pressure upon the renal vessels, *dysphagia* from pressure upon the œsophagus; *vomiting* from obstruction of the pylorus, *displacement* of the liver forwards, or of the heart upwards—though rare symptoms—may be likewise due to the same cause. The radial pulse is not often affected. Symptoms of constitutional irritation and impaired nutrition are rarely exhibited, and appear only at the termination of protracted and painful cases, associated with great suffering and want of sleep.

The *physical signs* are those discoverable by palpation, percussion, and auscultation. The tumour usually projects to the left of the mesial line, and tends to descend; it is smooth and elastic, communicating to the hand alternate movements of lifting and expansion with increasing tension, and of subsidence with relaxation. The pulsation is all but invariably single, and synchronous with the radial pulse; it is limited to the tumour, and occasionally accompanied by thrill. Pressure upon the aorta below the tumour will increase the force of impulse, diminish or abolish the thrill, and arrest the collapse. In a few recorded examples the tumour was hard and uneven on the surface, and non-expandible, and in a still smaller number no pulsation was perceptible, the aperture of communication with the artery having been blocked, or the vessel compressed on the proximal side by the growth of the aneurism itself. Owing to the position of the hollow viscera in front, and the mass of lumbar muscles behind, the evidence from percussion is less conclusive in regard to abdominal than thoracic aneurism. If, however, the abdominal muscles be relaxed, and the stomach and bowels free from flatus, absolute dulness to the extent of the tumour may be detected. A sound, single or double, as distinguished from murmur, is rarely heard in front in connexion with abdominal aneurism; whereas the existence of sound without murmur, and usually double, at a point of the posterior wall of the abdomen corresponding to the tumour, is the rule, and, when detected, is of the utmost diagnostic value. Murmur in the recumbent posture is rarely absent in front; it is single, blowing, prolonged, post-systolic, and not transmitted into the vessel beyond. It may, however, be musical, or it may present both these characters, but at dif-

ferent points of the tumour; in one instance it was of a buzzing quality. Should the aneurism have taken an exclusively backward course, which is the exception, a single murmur, not audible in front, may be heard in the back. In a few recorded cases a double murmur has been heard over the aneurism in front. In the erect posture the murmur is usually suspended; but in a few published cases it was audible in both the erect and the recumbent posture, and in one at least in the erect posture only. These peculiarities depend upon the various conditions of the sac, its orifice, and its contents. A small aneurism engaging the posterior wall of the vessel only, and eroding the vertebra, may be latent as to physical signs, though attended with severe dized pain in the back.

DIAGNOSIS.—The diagnosis of abdominal aneurism has reference mainly to its physical signs. Strong pulsation of the aorta, simulating that of aneurism, may exist in connexion with hysteria, uterine or intestinal irritation, dyspepsia, or copious hæmorrhage. But in all these cases, irrespectively of the positive and specific evidence presented by each, throbbing exists throughout the aorta, and is propagated into the main arteries of the lower limbs, whereas it is localised in aneurism; and a careful exploration of the aorta, if necessary under the influence of chloroform, will show that its dimensions are at all points normal. In these cases, too, although a murmur may be produced by strong pressure with the stethoscope, it does not exist when pressure is withdrawn. A cancerous or other tumour pressing upon the aorta may likewise produce murmur, and may exhibit pulsation communicated from the aorta, but in most cases both these phenomena are promptly arrested by placing the body in the prone position, the tumour, in that position, gravitating from the vessel. The fixed local pain in the back, aggravated by pressure and motion, may be simulated by spinal rheumatism, and the paroxysmal visceral pain by biliary colic. The differential diagnosis must rest upon the specific evidence in each case, and upon the absence of the signs of aneurism.

Aneurism of the Branches of the Abdominal Aorta.—The branches most liable to aneurism are the common iliacs and their divisions; the celiac axis and its branches; the renal and the superior mesenteric. *Aneurism of the Iliac Arteries* belongs to the domain of surgery, and will not be further referred to here. *Aneurism of the Celiac Axis* and of its branches of division, and of the *Superior Mesenteric Artery*, are, in addition to the ordinary signs, equally characterized by mobility; and the first two varieties by jaundice, hæmatemesis, and melæna, from pressure. Renal aneurism may cause obstruction in the kidney or renal colic by pressure on the structures in the hilus.

DURATION AND TERMINATIONS.—The duration of life in cases of abdominal aneurism has, in the writer's experience, varied from fifteen days to eleven years. Death occurs usually (1) by rupture of the sac into (a) the retro-peritoneal space; (b) the cavity of the peritoneum; (c) the left pleura or lung; (d) the intestinal canal; (e) the inferior vena; (f) the psoas muscle; (g) the

pelvis of the kidney; (h) the spinal canal, or (i) the ureter, biliary passages, or œsophagus. and in the order of relative frequency just given; or (2) by exhaustion or syncope. The duration of life after the rupture of the aneurism has ranged from a few minutes to several weeks. A consecutive false aneurism of the retro-peritoneum is specially characterised by feeble pulsation of the tumour, and diminished or arrested circulation in the femoral artery of one of both sides.

TREATMENT.—The *Curative* treatment of abdominal aneurism may be considered under three heads—*Mechanical, Postural* and *Dietetic*, and *Medical*. Mechanical treatment consists in pressure applied to the aorta on the proximal side of the sac, or simultaneously on its proximal and distal sides, by means of tourniquets, so as completely to stop the circulation. The bowels should be first well moved and freed from flatus, and during the continuance of pressure the patient should be kept under the influence of chloroform or ether. Five cases, if not more, in which a cure was effected by these means have been reported. The object sought to be attained being that of effecting rapid coagulation in the sac, the period during which pressure needs to be continued in these cases varies from three quarters of an hour to ten hours and a half. Where space for the application of proximal pressure does not exist, distal pressure alone may be tried. Under all circumstances, pressure must be used with circumspection, as inflammation of the peritoneum or of the bowels may result from it.

Billingham introduced the plan of treatment by posture and restricted diet. Under this plan perfect repose of mind and body is, as far as practicable, to be maintained, the bowels being kept moderately free, and the dietary restricted to 10 oz. of solids and 6 oz. of liquids daily. According to the method of Mr. Tufnell, which is based upon the same principle, but is more rigid, the patient is strictly confined to the horizontal posture for a period varying from eight to thirteen weeks, as determined by the effect upon the aneurism, movement in bed being effected with caution; whilst, by a special arrangement, the bowels and the bladder may be evacuated without disturbance of the body. For breakfast, 2 oz. of white bread and butter, with 2 oz. of cocoa or milk, are allowed, for dinner, 3 oz. of meat, with 3 oz. of potatoes or bread, and 4 oz. of water or claret, and for supper, 2 oz. of bread and butter, and 2 oz. of milk or tea. The total amount in the twenty-four hours would be, solids 10 oz., liquids 8 oz. This system might be in some degree relaxed if the patient prove restive. Mild laxatives and opiates as required are the only medicines used. Ten cases of the successful treatment of aortic aneurism by this method have been reported by Mr. Tufnell. Abdominal aneurism was solidified in two instances, after treatment extending over thirty-seven and twenty-one days respectively.

Of the various medicinal agents used with a view to favouring or effecting a deposit of laminated fibrin in the sac, acetate of lead, iodide of potassium, scodite, and ergotin (hypodermically), alone claim attention. Iodide of potassium may be given with advantage in doses

of 10 to 20 grs. three daily, with a view to reducing vascular tension, and thereby relieving pain and promoting deposition in the sac, whilst perfect rest in the recumbent posture and a restricted dietary are observed. The latter are, however, the more important factors in the treatment. Dr. G. W. Balfour has reported several cases successfully treated by means of iodide of potassium; and recently an example of a similar kind has been published by Dr. Dyce Duckworth. Dr. Grimshaw has lately had an example of cure mainly through the use of aconite. At the same time the allowance of liquids must be reduced to the lowest possible standard, whilst excretion is promoted. Alcoholic stimulants may be given in small quantity and at long intervals, if the pulse exhibit debility and the patient complain of a sensation of sinking, otherwise they should be prohibited.

The *Palliative* treatment as applied to Abdominal Aneurism will be found described in the article *Acute Diseases of the Aorta*. The application of a few leeches, followed by a warm poultice, is very efficacious in relieving pain. The hypodermic use of morphia is still more rapidly effective. THOMAS HAYDON.

ABDOMINAL TYPHUS.—A synonym for Typhoid Fever. See TYPHOID FEVER.

ABDOMINAL WALLS, Diseases of. But little more will be needed in this article than to give a brief outline of the nature of the affections to which the abdominal walls are liable, as most of these are but local forms of diseases which are fully described in other parts of this work. The parietal peritoneum will be excluded from consideration, as its morbid conditions are treated of separately.

1. **SUPERFICIAL AFFECTIONS.**—*a* The skin covering the abdomen may be the seat of various eruptions. The rash of typhoid fever is chiefly observed over this region. *b* When the abdomen is greatly enlarged, its cutaneous covering becomes stretched and thinned, often presenting a shining appearance; this may even give way, so that it exhibits superficial cracks or fissures. If it has been distended for a considerable time or on several occasions, as after repeated pregnancies, the skin becomes impaired in its structure, and is often the seat of permanent white lines or furrows—*lineæ albicantes*. In this connection allusion may be made to the umbilicus, which, in certain forms of distension of the abdomen, may become pouched out, everted, or actually obliterated. *c* The veins of the skin frequently become enlarged and tortuous, when the return of the blood which is normally conveyed through them is in any way impeded. The particular vessels which are distended will necessarily depend upon the seat of the obstruction. *d* The cutaneous sensibility over the abdomen is sometimes materially altered. In certain nervous diseases it may become more or less impaired or lost; but the most important deviation is a marked increase of sensibility—*hyperæsthesia*—which is occasionally observed in hysterical females, and which may simulate more serious affections, particularly peritonitis, especially if it is accompanied with symptoms of much depres-

sion. This condition is characterized by extreme *superficial sensibility* or tenderness of the abdomen, the slightest touch being resented; but if the patient's attention can be taken off, and deep pressure be then made, this is borne with little or no indication of distress. The aspect of the patient, the presence of other symptoms indicative of hysteria, and the absence of pyrexia, usually serve to distinguish this affection from others of a graver nature. The surface of the abdomen may also be affected with neuralgia, which is sometimes very severe.

2. **SUBCUTANEOUS ACCUMULATIONS.**—*a* The chief morbid condition coming under this head is *œdema* or *dropsy* of the subcutaneous tissue. This generally follows anasarca of the legs, and may be associated with ascites. The fluid tends to collect especially in the lower part of the abdominal walls and towards the flanks. The skin often presents a white pasty aspect; the abdomen may be more or less enlarged; the umbilicus appears depressed and sunken, if the œdema extends up to this level; the superficial structures put on pressure, and yield the peculiar sensation of dropsical tissues; and the percussion note is frequently muffled. *b* The abdominal subcutaneous tissue is, in many persons, the seat of an abundant collection of fat, which may be important from its causing general enlargement, and simulating or obscuring other more serious morbid conditions which enlarge the abdomen.

3. **AFFECTIONS OF THE MUSCLES AND APONEUROSIS.**—*a* The abdominal walls may be the seat of muscular rheumatism, which is particularly likely to follow undue straining, such as that caused by violent coughing or vomiting. It is characterized by pain sometimes severe, evidently located in the muscular and tendinous structures, accompanied with much soreness and tenderness. The affected parts are kept as much at rest as possible, and any action which disturbs them materially aggravates the pain. *b* As the result of violent strain, the muscular or aponeurotic tissues may be more or less torn or ruptured. As a consequence a protrusion of some internal structure may take place, forming a hernia. *c* The abdominal muscles are liable to be the seat of spasmodic contractions, cramp, or rigidity. These are not uncommonly excited in sympathy with grave disturbance of the alimentary canal, as in cholera. In certain painful internal affections also some of the abdominal muscles are occasionally kept in a state of more or less rigid tension, as if they were involuntarily contracted in order to protect the diseased parts underneath from injury. The spasmodic contractions in tetanus not unfrequently cause great suffering over the abdomen. *d* On the other hand, the abdominal muscles are occasionally paralysed, as the result of central nervous disease. The movements of respiration are then altered in character; while the expulsive acts in which the abdominal muscles naturally take part are much interfered with.

4. **RELAXED ABDOMINAL WALLS.**—All the structures forming the walls of the abdomen are often in a relaxed and flabby state, yielding to any pressure from within, so that the abdomen becomes enlarged and prominent, especially if,

as is frequently the case, this condition is associated with much flatulence. It materially weakens the act of defecation, and promotes constipation.

6. INFLAMMATION AND ABSCESS.—Local inflammation may be set up in any of the abdominal structures, and this may terminate in suppuration and the formation of an abscess. Purulent accumulations from within, as in cases of pelvic abscess, as well as certain abscesses originating in diseases of bones or joints, may likewise extend among the tissues of the abdominal walls, causing thickening and induration, or may make their way outwards, directly or through a sinus. Subsequently permanent sinuses or fistulae may be left.

6. The abdominal wall may be the seat of *extravasation of blood*; and various kinds of *tumour* or *new growth* may form in its structures.

FREDERICK T. ROBERTS

ABERRATION.—A divergence or wandering from the usual course or condition, applied in medicine chiefly to certain disorders of the mental faculties. See *INSANITY*.

ABORTION.—The act of *abortion* signifies the expulsion of the contents of the pregnant uterus before the seventh month of gestation. An *abortion* is a designation given to a fetus prematurely expelled. See *MISCARRIAGE*.

ABSCESS (*abscedo*, I depart) *SYNON.*: *Fr absces*; *Ger. Eiterheule*. *Græc.* *κυστήρ*.

DEFINITION.—A collection of purulent matter, one of the results of inflammation. See *PUG* and *INFLAMMATION*.

PATHOLOGY.—If the material which collects in a tissue as the consequence of inflammation softens and becomes liquid (suppuration), it does so either rapidly or slowly: if the former, the result is an *acute abscess*; if the latter, the abscess is termed *chronic* or *cold*. If the material thus softened and forming pus, often mingled with fragments of dead tissue, is limited by condensation of the parts around, which are usually consolidated by the products of inflammation, the abscess is said to be *circumscribed*; but if the surrounding parts in their turn soften, so as practically to offer no barrier to the pus, then the abscess spreads and is said to be *diffused*. In an *acute circumscribed abscess* the lymph which collects around it as the result of inflammation becomes organized and forms a sac (pyogenic membrane); and this, with the compressed tissue about it, is the wall of the abscess, consisting therefore of contents (pus), of a limiting sac, and of condensed tissue around. The resistance offered to the extension of the suppuration is greatest when the parts adjacent are dense and tough, such as bone and fascia; yet, as the pus in an abscess increases in quantity, probably by breaking down of the pyogenic layer, sufficient pressure is exerted to cause the most dense structures to yield, and an abscess will thus make its way even through osseous tissue. As might be expected, an abscess always advances in the direction of least resistance, and this extension is spoken of as its *pointing*. This pointing may be towards the surface of the body, but an abscess may direct itself towards a serous cavity, such as the peritoneum, or along a track of cellular tissue,

as when pus beneath the deep cervical fascia points into the mediastinum. On the side at which the abscess is pointing, its wall, as the resistance lessens, projects; and by ulcerative absorption the parts covering it become quickly thinner, until they and the abscess-wall give way and the pus escapes. In by far the greater number of cases this absorption of tissue before the pointing abscess is towards the surface, and it is by ulceration of the skin that the opening for the discharge of the matter is effected. The wall of the abscess then contracts, pus continuing for a time to be discharged; and in the end, aided by the resilience of the tissues around, the sac of the abscess is obliterated, and the orifice through which its contents were discharged heals by granulation process. To ensure this result the walls must be left at rest, or the granulations which cover them will fail to unite, and the obliteration of the sac will not then take place, as happens for example in the case of an abscess situated between the movable rectum on the one side and the ischium on the other, where the opposite abscess-walls are prevented from joining by muscular movements on the side of the bowel, and will only unite after such movements have been stopped by cutting across the muscular fibres which occasion them. The track which results from such failure of the healing of an abscess is called a *sinus* or *fistula*.

In a *diffused abscess* the inflammation of the parts around does not limit the suppuration by organization of the effused lymph, but such lymph, itself degenerating, forms more pus, and so the abscess extends rapidly and widely, unless checked by some barrier of dense tissue. In this way matter often spreads along tracks of cellular tissue, as along the course of veins, and in the subcutaneous structures. An abscess when formed between bone and periosteum, or otherwise hindered from reaching the surface by pointing also tends to diffuse itself by following the course of least resistance. In most of these cases by direct pressure upon the resisting tissue or by cutting off the blood supply (as of the skin when its subcutaneous tissue is infiltrated with pus), sloughing of the parts covering in the abscess ensues, oftentimes to a considerable extent, and so the pus eventually makes its way to the surface. It is these abscesses, spreading along tracks of tissue before they can reach the surface, which are apt, however, when involving certain parts, such as the course of some of the lumbar nerves to burst into a serous cavity with fatal consequences.

A *chronic abscess* begins in some local inflammation without active symptoms, such as results in the deposit of aplastic lymph and subsequent ulcerative changes, as caries of bone, the irritation leading to suppuration. The formation of matter proceeds in a languid manner, so that it is only by slow degrees that it collects in any considerable quantity, although eventually these chronic abscesses may acquire great size. They slowly point, and in their tardy advance occasionally traverse even serous cavities, which have been first obliterated in the line of transit by adhesive inflammation of their opposed surfaces. In this way an abscess formed in the liver (and this holds good also for those of a more acute chara-

(ter) may travel through the layers of the peritoneum, and may point through the anterior wall of the abdomen.

When an abscess discharges, its contents are seen to be either a thick yellow (*laudable*) pus, or pus stained with blood, or otherwise coloured, such as black or bluish-green, or the pus may be thin, almost watery, mingled with flakes of lymph; it may be inodorous or fetid, or irritating to the touch (*ichorous*). Abscesses may also contain shreds of tissue, or foreign bodies, or masses of inspissated pus, as hard occasionally as calculi, or fragments of dead bone, or calculi of various kinds. Sometimes a chronic abscess ceases to enlarge and if the irritation which occasioned it comes to an end, it may diminish by absorption of the fluid part of its contents, the solid drying up into a shrunken putty-like mass. It may remain in this state without giving rise to trouble, or it may become again the seat of suppuration by the formation of what under such circumstances has been termed by Sir James Paget a *recurrent abscess*.

The progress of any abscess is largely influenced by the state of the general health. In persons otherwise robust an abscess commonly runs an acute course, in those weakened by acute illness, such as scarlet fever or typhus, they form quickly, but are slowly recovered from, and severely tax by an exhausting discharge the powers of the patient. Persons in feeble health, hereditary or acquired, usually suffer from the chronic and diffused forms; and chronic affections of internal organs, as of the liver or kidneys, are not unfrequently associated with the development of such abscesses.

ÆTIOLOGY.—The cause of an *acute* abscess may be an injury, such as a blow or pressure, as often happens in persons weakened by continued fever, exposure; or the irritation of a foreign body, or that of a poison introduced from without. In the last case the abscess is often diffused. Abscesses running an acute course may also be due to a foreign body or to an irritant from within, as when it follows necrosis of a portion of bone, or the escape of urine into the tissues of the perineum. It also arises in connection with blood-poisoning as in various fevers, and affections distinguished as septic. The cause of a *chronic* abscess is usually found in changes which go with deposits of a tuberculous character, or it is found in the changes which slowly occur around an irritating body, such as a renal calculus, or chronic inflammatory changes may culminate in one of these collections of matter. They may also form in parts which are long congested in connection with obstructed vein circulation (*varix*); and they may follow, or conditions closely allied may follow, the occlusion of a main artery and the consequent cutting off of the supply of blood to a particular region.

SYMPTOMS.—The symptoms of an *acute* abscess are those of a local inflammation, with constitutional disturbance if the abscess is of any size; followed by a sense of cold or actual shivering, with increase of pain and swelling, tenderness, and throbbing. The tenderness can be recognised in the case of most abscesses; and, if pus is formed anywhere near the surface, the presence of the fluid is detected by its fluctua-

tion. The severity of the pain is much influenced by the site of the abscess, as when the pus is held down and hindered from pointing by dense structures, such as fascia. Special symptoms may also arise in connection with the situation of the suppuration, as when urgent dyspnoea is caused by the pressure on the larynx of an abscess deeply seated at the base of the tongue. A *diffused* abscess, if subcutaneous, is recognised by its rapid spreading, and may be suspected if other signs point to a part as the site of the abscess in which diffusion is the rule, as, for instance, by the side of the rectum in the ischio-rectal fossa.

Of *chronic* abscess there is seldom in its early stage any evidence. The symptoms, if any, are those of failing health, and for the rest are marked by those of other changes from which the abscess is an outcome. Thus in disease of the hip joint, or of the spine, unless an attack of shivering chances to attract attention, an abscess is not as a rule suspected until it has broken through its first limits and has attained considerable size. It is not worth while to attempt to distinguish between chronic abscess and other swellings, such as extravasated blood or soft tumours, especially malignant tumours, for if a doubt in any case arises, it can be at once solved by the introduction of a grooved needle or of a fine trochar into the swelling. The true pulsation in an aneurism sufficiently tells its nature, and is not easily mistaken for the impulse sometimes given to an abscess by an adjacent artery.

VARIETIES.—The chief local varieties of abscesses which are likely to be met with in medical practice may be thus arranged: 1. Subcutaneous or more deeply seated abscesses in the limbs, in connection with low fevers, erysipelas, pyæmia, &c. 2. Abscesses of local origin in the walls of the abdomen or chest. 3. Abscesses originating in serous membranes. 4. Certain special abscesses associated with diseased bone, *e.g.*, psoas and lumbar abscess. 5. Abscesses formed in the cellular tissue around organs, *e.g.*, peri-nephritic, peri-cæcal, &c. 6. Abscesses originating in inflammation of organs, the chief of which include hepatic, renal, pyætic, pulmonary, mammary, cerebral, splenic, pancreatic. 7. Obscure abscesses formed in the deep cellular tissue, *e.g.*, retro-pharyngeal, ischio-rectal, mediastinal. 8. Glandular abscesses, which are usually chronic and of a scrofulous nature.

TREATMENT.—The treatment of an *acute* abscess consists in rest, soothing local applications, and the use of remedies to allay pain and constitutional disturbance, if the latter exists. As soon as the presence of pus is recognised the abscess must be opened, if possible where the matter is most dependent; and as soon as its contents have escaped all troublesome symptoms will usually disappear. The opening is needed to relieve pain, and to prevent in some cases diffusion, and sometimes to relieve urgent distress, as when dyspnoea is caused by the pressure of an abscess upon the air-passages. It is also desirable to open an abscess to avoid the considerable scarring which must result if the matter is left to escape by ulceration and sloughing of the superficial tissues. If it is important to

avoid the scar of an incised wound, an abscess may be punctured in several places with a grooved needle, when the punctures, if kept open, will effectually drain off the pus, and the marks left will in the end be scarcely discernible. In most cases, however, it is necessary to open an abscess by an incision: a narrow double-edged knife should be used; and if the matter is deeply seated, the superficial parts only need be cut, the deeper being torn through, as Mr. Hilton recommends, by dressing forceps: the risk of dividing important structures, as in the neck, is thus avoided. After the pus has escaped, the wound should be kept open by means of a drainage tube (unless the abscess is of insignificant size), which is conveniently made by introducing a twisted slip of thin gutta-percha tissue or of oiled silk, and should be covered with carbolic oil on lint, or with a poultice of linseed and ferralum. Some surgeons protect the wound whilst operating by means of the carbolic spray or by a piece of linen steeped in carbolic lotion (1 in 20), or take other antiseptic precautions. The drainage tube should be withdrawn after the first day if the abscess is superficial, but if the pus has been deeply seated it should be only gradually withdrawn, portions being cut off as the abscess contracts. If a foreign body has caused the formation of the abscess, it must be sought for and removed before the suppuration can be expected to cease. Occasionally the vascular wall of an abscess bleeds freely, or a vessel is opened in the progress of the affection: the hæmorrhage usually ceases on laying the abscess freely open, but if this does not suffice it may be permanently controlled by pressure, and the cases are rare in which further operative interference is called for. Inflammation of the ear used not infrequently to follow the discharge of its contents, but under the treatment now employed such an occurrence is unknown. During the healing of any considerable abscess the general health should be attended to, and tonics and change of air may be useful to expedite recovery.

Diffused abscesses, whether subcutaneous or more deeply seated, require free incisions as soon as suppuration is even suspected, so as to avoid the damage which results from their spreading and from the sloughing of tissue, as of the skin, which will otherwise occur, especially with those due to poison introduced into the system or those caused by infiltration of urine. These abscesses sometimes lead to fatal results.

A chronic abscess may have its contents drawn off by the aspirator; or it may, when it has come near the surface, be opened, drained, and dressed with carbolic oil on lint, without any risk of constitutional disturbance, but its ultimate closing will depend upon the removal of the cause; if, for example, it is due to disease of a joint, it cannot be cured until the disease in which it has originated has in some way ended.

GRAN.—An abscess after being opened may contract until it forms a narrow track, sinus or fistula, leading to the site of primary irritation. Such a track has a dense fibrous wall from which non-purulent fluid escapes: it may also convey secretions, as from the liver (*hepatic fistula*) or

stomach (*gastric fistula*), or excretion, as from the kidneys; or it may simply carry out the pus which forms around some irritant at the deep extremity, such as a foreign body, a portion of carious or of necrosed bone. Some such fistulae are due to the movements of adjacent muscles preventing union of the abscess walls. Unless the cause of the sinus can be removed, as by extracting necrosed bone, these fistulous tracks are difficult to manage, requiring special treatment according to their situation. Other *fistulae* are those forming communications between mucous canals (*recto-vesical, vesico-vaginal fistulae*), and these need special treatment, such as plastic operations and operations diverting the course of excreta escaping through unnatural channels.

The tissue about healed abscesses, scar-tissue generally, and tissue spoiled by inflammation, are apt on slight provocation to inflame and suppurate, and to those collections of matter the term '*residual*' has been applied. The treatment of such abscesses in no way differs from that of others, and they usually heal in the ordinary manner.

G. W. CALKINS.

ABSINTHISM.—**DEFINITION.**—The condition induced by the undue imbibition of absinthe.

From the mode in which absinthe is taken, we should expect that the symptoms induced by its excessive consumption would be generally obscured by, and intermixed with those of alcohol (*see ALCOHOLISM*). That it has a special effect on the organism, and that this may be diagnosed from alcoholism, has been pointed out by Motet, Magnan, and other French physiologists, and the writer last-mentioned has clearly exemplified its action by numerous experiments on dogs. In persistent absinthe-drinkers vertigo and epileptiform convulsions are marked symptoms, and come on much earlier than when alcohol in other forms is habitually drunk. *Hallucinations* occur also without any other symptom of delirium tremens; and, when tremors coexist, these are limited more particularly to the muscles of the arms, hands, and upper extremities. Absinthe acts chiefly on the cervical portion of the spinal cord, and thus readily explains the special symptoms arising from its regular use. • JOHN CROW.

ABSORBENT AGENTS.—**DEFINITION.**—In *Surgery*, absorbents are substances used to absorb fluids, as sponges, charpie, or tow; in *Medicine*, drugs which neutralize excessive acidity in the stomach—a synonym for alkalis (*see ALKALIS*). The term is sometimes also made use of to designate remedies, such as the preparation of mercury and iodine, which are believed to possess the property of promoting the absorption of morbid products.

ABSORBENT VESSELS and GLANDS. **DISEASES OF THE LYMPHATIC SYSTEM, DISEASES OF; also BRONCHIAL, and MESENTERIC GLANDS, DISEASES OF.**

ACARUS.—*Acari* or *Mites* constitute an order of the class *Arachnida*, several species of which are parasitic. The *Acarus scabiei* or *Sarcoptes humanus*, and the *Acarus folliculorum*, are

more properly the *Steatocion folliculorum*, are the only human parasites belonging to this family.

DESCRIPTION.—1. The *ACARUS SCABIEI* is a small roundish animal, just visible to the naked eye. Examined under the microscope it is seen to be flattened and to resemble a tortoise in shape; when fully developed it has eight legs, and on its under surface are scattered filaments and short spines, which are for the most part directed backwards. The female is larger than the male, and is provided with terminal suckers on the four anterior legs, while filaments occupy a similar position on the posterior ones, in the male, however, the two extreme hind legs have suckers like those of its fore limbs. The young *Acarus* has only six legs, the two hindmost ones, which are distinctive of the sex, being wanting. It acquires these after shedding its first skin. The male *Acarus* lives near the surface of the skin, while the female burrows within the cuticle, and deposits from ten to fifteen eggs in the cuculus or burrow, these eggs hatch in about a fortnight. The young *Acarus* escape from the burrow, but the parent does not leave it, and dies when she has finished laying eggs. The *Acarus scabiei* is the cause of the skin-affection termed *Scabies* or *Itch* (see *SCABIES*).

2. The *ACARUS FOLLICULORUM* is a very minute parasite commonly found in the sebaceous and hair follicles of the face, but its presence can hardly be regarded as indicating disease. In this animal the head is continuous with the thorax, and to the latter are attached eight very short legs, each armed with three strong claws. On each side of the head are short jointed palpi. The abdomen varies in length from twice to three or four times that of the thorax; it is pointed at its distal extremity. The presence of this parasite in the follicles of the skin is quite unimportant.

ROBERT LIVING.

ACCOMMODATION, Disorders of.—See *VISION, Disorders of*.

ACEPHALOCYST (ἀ, priv; κεφαλή, a head, and κύστις, a bladder).—A headless cyst or hydatid.—This term was formerly much employed to distinguish the true hydatid from all those bladderworms that are furnished with a head visible to the naked eye. The expression is a misnomer and should be abandoned, since it is only fairly applicable to such hydatids as have failed to develop the so-called heads internally. The *Acephalocystis endogena* of John Hunter and the *A. exogena* of Kuhl are merely varieties of the true hydatid (*Echinococcus veterinarius*, or *E. hominis*). See *HYDATIDS, ECHINOCOCCUS*, and *BLADDERWORMS*.

T. S. CORNOLD.

ACHOLIA (ἀ, priv., and χολή, bile).—Absence or deficiency of bile. See *BILE, Morbid states of*.

ACHOR.—A small follicular pustule of the scalp Willan's definition is as follows:—'A small accumulated pustule containing a straw-coloured matter, which has the appearance and nearly the consistence of strained honey, and is succeeded by a thin brown or yellowish scab.' Both the pustule and the scab are constituents of the disease *Torquet*. The word has fallen into disuse but is preserved by Schenck in the name 'Acho-

ria' assigned by him to one of the varieties of parasitic cutaneous fungi. The Greek word *αχρη* signifies scurf, or dandruff; *αχρη* meaning chaff.

ERASMUS WILSON.

ACHORION (αχρη, scurf) is the name given to one of the three principal dermatophytes or epiphytes of the skin. It is the constituent of the crusts of Favus (Achor), and belongs to the group of fungoid plants denominated *Didymium*. It consists of spores, sporidia or tubes filled with spores, and empty branched tubes or mycelium.

Achorion was the first discovered of the epiphytes of the skin, and in compliment to one of its early observers, Schönlein, has been named *Achorion Schönleini*. It is supposed to be the agent of contagion in Favus; it has also been found in the loose cell-structure beneath the nail in Onychomycosis.

ERASMUS WILSON.

ACHROMA (ἀ, priv., and χρώμα, colour). Absence of colour, an achromatous or colourless state of an usually coloured tissue, due to absence of pigment. In reference to the skin Achromia is synonymous with Leucoderma, Albinism, and Aliphsia. See *PIGMENTARY SKIN-DISEASES*.

ACHROMATOPSIA (ἀ, priv.; χρώμα, colour, and ὄψις, sight).—More or less complete inability to distinguish colours from each other. See *VISION, Disorders of*.

ACIDITY.—Acids are constantly passing out of the body by the lungs, the skin, and the kidneys. These acids, if we except the small quantity introduced from without in the form of acid salts of certain articles of food, are formed within the body by the disintegration and oxidation of the tissues and food. If the oxidation of organic substances in the system were complete, the sole products of their combustion would be carbonic acid, water, and urea, but as this oxidation is never actually complete, other products, as lactic acid, oxalic acid, uric acid, etc., are formed; and the increased or diminished production of these intermediary products may be regarded as the measure of the completeness with which the oxidation processes are being performed in the body. The quantity of acid matter passing through the blood on its way to the lungs, the skin, and the kidneys is considerable; since it has been shown approximately, that a healthy man of eleven stone weight, under ordinary circumstances, passes by the two first channels an average of 890 grammes (about 28 ounces) of carbonic acid daily, and that the acid excreted by the kidneys in the same period is equivalent to two grammes (about 31 grains) of crystallised oxalic acid; whilst the volatile fatty acid's passing off with the sweat have not yet been satisfactorily calculated. It is evident that if the regular elimination of this acid, by any of these channels, be interfered with, it will tend to accumulate in the system. Acidity, or excess of acid in the body, therefore depends on two causes:—1. *Excessive formation*, the result of incomplete oxidation of the elements of the tissues and the food. 2. *Deficient elimination of acid* formed either in normal or abnormal quantities. Both these causes, however, are generally found acting in conjunction. Oxidation is imperfectly performed, when an insufficient quantity of oxygen

is introduced into the body, owing to insufficiency of the respiratory act, the result of disease or of sedentary habits; or when the blood is poor in red corpuscles, the carriers of oxygen, as in leucocythæmia; or from functional derangement of some large gland, as the liver, where oxidising processes are extensively wrought. Again, the materials submitted to the influence of the oxygen within the body may be so increased, as is the case in febrile conditions, or in general plethora induced by over-feeding and insufficient exercise, that the supply of oxygen may prove insufficient for their complete combustion. Defective elimination of the acids formed within the body is due either to diseased conditions which prevent, or to want of the physiological stimulus which excites, the lungs, skin, and kidneys to exercise their respective functions properly. It will be seen therefore, that acidity may arise in consequence of the disturbing influence of disease, or may be acquired or inherited as the penalty of transgression of certain laws of health—as the result of unfavourable hygienic conditions. In the former case, acidity is only secondary, and is generally subordinate to the disease producing it, and has rarely to be considered apart from it; whilst in the latter instance acidity is usually at first the only trouble, leading, however, if disregarded to secondary mischiefs.

Errors.—The mucous membranes and skin chiefly suffer in acidity. The former become subject to catarrh, produced, no doubt by the irritating presence of the acid. Acidity may thus cause bronchitis, gastro-intestinal catarrh, and catarrh of the genito-urinary tract. Sometimes the acid is poured out in such quantities from the mucous membrane of the stomach as to be ejected from the mouth. In these cases digestion is considerably interfered with by the too acid condition of the gastric juice. Sometimes, however, this acidity of the stomach is produced by an opposite condition—the deficiency of the digestive fluid, and consequent acid fermentation of the food. Abnormal acidity of the urine produces not only catarrh of the urinary passages, but by decomposing the salts of uric acid causes a deposit of insoluble uric acid in the passages, thus giving rise to attacks of gravel or leading to the formation of a calculus. Acidity manifests itself in the skin by attacks of erythema, herpes, eczema, and urticaria. Rheumatism, too, may be considered as a disease resulting from the formation of acid, affecting chiefly fibrous and serous membrane; no one can witness the enormous quantities of acid sweat poured out, and the highly acid urine, in the acute form of this disease, without acknowledging that an increased formation of acid is taking place somewhere in the body; though perhaps unwilling to commit himself to accept any of the views hitherto advanced as to the nature of the acid.

Determination of Acid.—For clinical purposes an estimation of the acidity of the urine furnishes the physician with an approximate clue as to the amount of acid formed in and passing out of the body. This is done by collecting the urine the twenty-four hours, placing 100 c.c. of it in a beaker, and then adding a solution

of sodium hydrate, standardised so that 1 c.c. = .01 gramme of crystallised oxalic acid, from a Mohr's burette, till the fluid is neutralised; the number of c.c.'s of the standard solution required to effect this is to be multiplied by .01, which gives the percentage acidity in terms of oxalic acid; to ascertain from this the total amount of acid in the twenty-four hours' urine is only a matter of calculation. Too much dependence must not, however, be placed on the urine as a means of estimating excess or deficiency of acid in the system; it sometimes happens that in highly acid conditions the urine is alkaline. This, as Dr. Bence Jones has shown, may occur when large quantities of acid fluid are poured out of the stomach, and Prout long ago observed, that in the eczema of gouty persons the urine, so long as the disease persisted, was either of low acidity or alkaline, but that the subsidence of the eczema was frequently followed by an over-acid condition of the urine, accompanied with renal and vesical catarrh.

TREATMENT.—The general indications for the treatment of acidity consist in the promotion of oxidation, and the elimination of the acids formed. Active habits, which promote the pulmonary and cutaneous functions, should be encouraged. The diet should be just sufficient to meet the physiological requirements of the body, it should consist chiefly of fish, fowl, game, and eggs, saccharine and starchy articles being excluded. Sweet and cheap wines should be avoided, for those who cannot afford to purchase good wine, pure spirits and water is the best substitute. Carlsbad salts or Friedrichshall water may be given if there is much abdominal plethora; the habit of taking mercurials as a relief for this condition is to be deprecated. Alkaline medicines are frequently administered with a view of neutralising the effects of acid, their employment for this purpose seems, however, questionable. Dr. Parkes has stated that the administration of bicarbonate of potash (a favourite remedy in acid diseases), though rendering the urine alkaline, in reality increases very largely the excretion of the organic acids. This is not to be wondered at when we consider that the bicarbonate, although alkaline in reaction, is in constitution an acid salt. The nitric and hydrochloric acids, given in moderate doses about one hour before meals, certainly have a powerful oxidising effect, and diminish the quantity of uric acid excreted in the urine. In cases where the acidity is manifestly due to defective oxidation consequent on poverty of blood from diminution of the red corpuscles, iron and food must be freely given.

ACIDS.—**DEFINITION.**—Substances which combine with alkalis, and destroy their power of turning red litmus paper blue. Most of the acids also redden blue litmus, and have a sour taste; but some, for example, carbonic acid, possess neither of these properties.

ENUMERATION.—Acids may be divided into *Inorganic* or *Mineral*, and *Organic*. The mineral acids used in medicine are Carbonic, Hydrochloric, Nitric, Nitrohydrochloric, Phosphoric, Sulphuric and Sulphurous acids. The organic acids thus employed include Acetic.

Benzoic, and Carbolic, Citric, Gallic, Hydrocyanic, Lactic, Salicylic, Tannic, Tartaric, and Valerianic.

ACTION.—The stronger acids—Sulphuric, Nitric, Hydrochloric, and Glacial Acetic acids—destroy animal tissues, and act as caustics when applied to the surface. When swallowed, they produce the symptoms of irritant poisoning. (See POISONS.) An antidote for these poisons which is always at hand is carbonate of lime, in the form either of whiting or of plaster chipped from the nearest wall. Other antidotes are alkaline carbonates and bicarbonates, milk, oil, and soap. Diluted acids, taken into the mouth, increase the secretion of saliva, and hydrochloric acid forms an important constituent of the gastric juice, without which digestion does not go on. When absorbed into the blood, dilute acids act on the heart generally, slowing its pulsations and reducing the temperature. They are excreted in the urine and milk.

Uses.—Nitric acid is employed as a caustic application to piles, to poisoned wounds, and to spreading or unhealthy sores. Glacial Acetic acid is used to destroy corns or warts. Diluted Acetic acid or vinegar is applied as a lotion to relieve headache; to allay the itching of prurigo, lichen and psoriasis, to check perspiration; and sometimes to lessen the appearance of exanthematous eruptions. Diluted acids, especially Citric, Tartaric, and Hydrochloric, are administered in fevers as refrigerants, because they relieve the dryness of the mouth, and diminish the thirst by increasing the secretion of saliva, as well as lower the temperature and pulse-rate. Under the like circumstances, the organic acids, Acetic, Citric, and Tartaric, when combined with alkaline carbonates in a state of effervescence or otherwise, form agents which act on the skin and kidneys. In febrile conditions, anæmia, and some forms of dyspepsia, the proportion of acid in the gastric juice is insufficient for the proper digestion of food, and the administration of dilute Hydrochloric acid, immediately before or after meals, is useful both by aiding digestion and by preventing the formation of butyric and other acids, which give rise to sour eructations. Nitro-hydrochloric acid, before meals, is likewise beneficial in preventing acidity. It appears to have some action on the liver, and is used both internally and externally as a lotion or footbath in jaundice and biliousness. It generally relieves the frontal headache common in young females, which is felt just above the eyebrows, and not accompanied by constipation. Dilute acids, especially Aromatic Sulphuric acid, are useful in checking diarrhoea, colliquative sweats, hæmorrhages, and mucous discharges. By lessening the alkalinity of the urine, they tend to prevent the formation of phosphatic calculi, phosphoric and nitric acids being most frequently employed for this purpose. Care must be exercised in their administration to nursing mothers, as they are excreted in the milk, and sometimes cause griping and diarrhoea in infants at the breast. Several acids have a special action of their own, and are considered under their respective groups, such as Hydrocyanic acid, which is a sedative, Carbolic,

an antiseptic; Salicylic, an astringent; Gallic and Tannic, astringents. T. LAUDS BARNES.

ACINETHIA (ἀκίνησις, priv., and κίνησις, motion).—A synonym for paralysis of motion, whether partial or general. See PARALYSIS, MOTION.

ACNE (ἀκμή, I bloom).—The ancient Greeks showed their appreciation of the morbid states of the integument by calling this disease *akmē*, the *fos ætatis* of their Latin translators; but in course of transmission the *μ* gave place to *ν*, and the original term to that by which the disease is at present known.

DEFINITION.—An inflammation of the hair follicles, or a folliculitis of the skin, associated with the development of the permanent hair of the body at and after puberty; its almost exclusive seat of manifestation being the face, the submastoid region of the neck, the sternal region of the breast, and the back and shoulders.

ÆTIOLOGY AND PATHOLOGY.—In its relation to other diseases of the skin, Acne is nothing more than a folliculitis; and folliculitis, however engendered, must always pursue the same pathological course. Hence folliculitis of the face, from whatever cause, especially if attended with papulation and suppuration similar to the acne of puberty, has likewise been termed *Acne*; such is the *Acne Rosacea* or *Gutta Rosacea* of adult life; and such are the varieties of folliculitis produced by iodine, bromine, and tar, which have been respectively denominated Iodine-, Bromine-, and Tar-Acne.

DESCRIPTION.—The pathological essentials of Acne are:—a languid and torpid skin; a tendency to accumulation of sebaceous matter within the follicles, congestion of the coats of the follicles and immediately contiguous structures; and the ordinary manifestations of inflammation, such as suppuration, infiltration, and solidification. From these, which are the ordinary signs of inflammation of the follicles, we derive the various subjective designations of the disease: for example, when accumulation of sebaceous matter, showing as a black point with little or no inflammation, is the leading feature, the condition is termed *Acne punctata*; when congestion and infiltration force up the skin into a conical pimple, *Acne coniformis*; when suppuration is present, *Acne pustulosa*; and when thickening and condensation display themselves, *Acne indurata*. The whole series, with the exception of *Acne indurata*, which represents a chronic disposition, may be called indiscriminately *Acne simplex* or *Acne vulgaris*, there being obviously no regular standard.

DIAGNOSIS.—Acne is a well-defined eruption, and not difficult of diagnosis, its most important features being:—its limitation to the period of life corresponding to and soon after puberty; and its dependence on a physiological process at that time taking place in the economy.

TREATMENT.—The treatment of Acne may be summed up in a few words:—Remove any exciting cause that may exist; improve the nutritive power of the individual and of the skin; stimulate, that is, give tone and vigour to the part locally. Our best general remedies are a

good hygiene, careful attention to diet and habits of life, ordinary tonics, and especially arsenic. The most efficient local application is sulphur, especially the compound hypochloride of sulphur ointment, which consists of a drachm of hypochloride of sulphur with ten grains of carbonate of potash, to an ounce of benzoeated lard. Arsenic is best administered as a combination of Vinum Ferri and Liquor Arsenicæ (viij-ij) three times daily at the end of meals.

ERASMUS WILSON.

ACONITE, Poisoning by.—See POISONS.

ACQUIRED DISEASES.—Diseases originating independently of hereditary transmission. See DISEASE, Causes of.

ACROCHORDON.—An outgrowth of the integument in the form of a slender cylinder, which may be compared to the loose end of a piece of string or cord—*akros* signifying a point or end and *chordē* a string. Such outgrowths are usually met with in a feeble state of the skin, and particularly in elderly persons, their common seat being the neck or trunk. They are at first sessile, but become elongated; and are sometimes bulbous at the extremity, and more or less pedunculated. Pathologically an acrochordon is composed of loose areolar tissue, firmer at the surface than within, and of a fine artery and vein, connected by a capillary loop or plexus, and sometimes a little ramified. It is popularly regarded as a wart, and in medical works is termed *verruca acrochordum*, but it differs from a wart very widely in structure. When acrochordones attain a size beyond that of a pea, they fall into the category of a soft tegumentary tumour or Molluscum.

TREATMENT.—This consists in snipping them off with scissors, or touching them with a strong solution of potassa fusa (equal parts). When numerous and minute, they admit of being shrivelled up and removed by means of liquor plumbi, or a lotion of perchloride of mercury two grains to the ounce. The latter, by its stimulating property, also arrests their formation.

ERASMUS WILSON

ACRODYNIA (*akros*, extreme, and *dynē*, pain). A dermatitis affecting the hands and feet, particularly the palms and soles, accompanied with burning heat, stinging and smarting pains, and numbness. The pains sometimes extend to the whole system, and there is more or less disorder of the digestive and assimilative functions. The redness is at first bright, then deeper tinted and brown, with considerable pigmentation of the rete mucosum. Occasionally there are pimples, pustules, and blisters, the cuticle desquamates, and is sometimes cast in a single piece; the disease running on for several weeks.

TREATMENT.—This should be directed to the regulation of the digestive and assimilative organs, and to the relief of local inflammation by means of water-dressing followed by bandaging with zinc ointment.

ERASMUS WILSON.

ACUPUNCTURE is an ancient mode of treatment for the relief of painful affections, now

but little used, consisting in the introduction of fine round needles through the skin, to a varying depth. It is said to have been introduced into this country from China or Japan, about 200 years ago. The needles used are about two inches in length, and are set in round handles, so that they can be introduced with a gentle rotatory movement. It is now employed solely in lumbago and sciatica, in which affections it undoubtedly gives relief. The operation is thus performed. The patient being laid upon his face, tender spots are sought for—in lumbago over the erector spine, and in sciatica along the course of the sciatic nerve. The needles are then pushed in vertically for a depth of from one and a-half to two inches, and allowed to remain for from half an hour to two hours. The number of needles employed may vary from one to six. In sciatica it is recommended, if possible, to make the needle actually penetrate the nerve. This is known by the patient complaining of sudden pain shooting down the back of the leg. The mode of action is uncertain, but in sciatica it has been supposed that the puncture of the nerve sheath allows the escape of fluid. Acupuncture has also been employed in painful neuritis following injury, but without much effect. In a modification invented by Bunschedt, forty punctures, about half-an-inch in depth, were made in an area of the size of a crown piece, by an instrument working by a spring. Oil of mustard diluted with olive oil was then painted on, which gave rise to an eruption like herpes. This was at one time in great repute as a quick remedy for all sorts of diseases. The term *acupuncture* is also applied by some to the introduction of needles into a cyst, in order to allow the fluid contents to escape, as in the treatment of ganglion, of hydrops in infants, or of hydatid cyst of the liver. Puncture of the skin for the relief of oedema or subcutaneous emphysema is sometimes called by the same name. For this purpose the ordinary three-cornered acupressure needle is more convenient than a round acupuncture needle, as the puncture resulting from it allows fluid to escape more readily.

MARCUS BECK.

ACUTE.—This word, when associated with a disease, signifies that such disease runs a more or less rapid course, and is generally attended with severe symptoms. It is also employed to express intensity of a particular symptom, as, for example, pain.

ADDISON'S DISEASE. *SYNON.*: *Morbus Addisonii*; *Bronzed Skin Disease*. Fr. *Melade d'Addison*; Ger. *Addison'sche Krankheit*.

DEFINITION.—In his original memoir on this subject, Dr Addison wrote:—'The leading and characteristic features of the morbid state to which I would direct attention are anæmia, general languor and debility, remarkable feebleness of the heart's action, irritability of the stomach, and a peculiar change of colour in the skin occurring in connection with a diseased condition of the supra-renal capsules.'

In reality, the general symptoms of the disease, as given above, outweigh in importance any pigmentary change whatever and it

is quite possible for the disease to run its course without any unusual deposit of pigment in any part of the body.

Addison's disease might, however, be defined as 'a constitutional malady characterised by great weakness and anæmia, with deposit of pigment in the skin and some other parts of the body, and accompanied by or depending on a specific morbid change in the supra-renal capsules.'

ÆTIOLOGY.—The constitutional or general nature of the malady must ever be borne in mind, though some of its factors are strictly local; but, though constitutional, it is not transmissible either (a) by contagion or infection, or (b) by inheritance. If, however, Addison's disease itself is never an inherited malady, it is in very many cases associated with a highly hereditary constitution, that of the tubercular or scrofulous type, and in such individuals accidents like falls or blows, which would fail to make an impression on stronger men or women, may suffice to set the morbid process in motion. In not a few instances the bodies of the subjects of this disease have been found perfectly healthy apart from the morbid change in the supra-renal capsules characteristic of the malady; and, in a certain number of cases, local abscesses seem to have been the starting-point of the specific changes in the capsules themselves. Addison's disease is, moreover, essentially one of early adult life, the great majority of cases occurring between fifteen and forty. It is much more frequent in men than in women, and seems, in a great measure, to be confined to the working classes.

SYMPTOMS.—It is not at all times nor in all instances an easy task to make out a perfect clinical history in a case of Addison's disease. The earlier symptoms are often so indefinite and so insidious that it may not be until the disease is fully developed that the patient seeks medical aid, and by that time the symptoms are usually unmistakable. It is different when the malady apparently originates in a fall or a blow, but even such a starting-point as this may only be sought for late in the history of the disease.

The mischief may be said to commence in most cases with a feeling of general weakness and of being unwell; the discolouration of the skin usually appears later, but may be the first prominent symptom. In a small number of cases the onset may be acute, with loss of appetite, sickness, headache, pain in the epigastrium, sometimes also vomiting and diarrhoea. When the disease has attained its full development the characteristics of the malady are most striking. Then the downcast, mournful look, the drooping shoulders and stooping gait, the arms hanging helplessly by the sides, and the slow and listless movements of the patient are strikingly impressive. If to this be added the darkening of the skin, the clear and pearly conjunctiva, and the breathlessness on exertion, we have almost all that meets the eye when such a patient presents himself. But to these, on enquiry, other important symptoms are easily added. The breathlessness will be found to be partly due to anæmia, partly to impaired innervation. From the same causes

in part, but not entirely, we find a quiet, stable action of the heart, readily giving place to palpitation. With these are usually associated pain and tenderness in the epigastrium and hypochondria, irritability of the stomach and nausea giving rise to retching, and frequently obstinate vomiting. Such modifications of breathing as sighing, yawning, or hiccups, are frequent. Again, from the anæmia, there is a strong tendency to giddiness and syncope, which last increases as the disease wears on, and, in many cases, carries off the patient when raising himself, or being raised in bed for the purpose of taking food or performing other necessary functions. This is not the invariable mode of death, for nervous symptoms, such as coma or convulsions, may usher in the final scene. When the prostration is great, the patient may be for some time before death apparently unconscious, but this is simply due to unwillingness to make the slightest exertion, owing to his profound weakness.

Throughout the whole disease the bodily temperature is diminished (97° – 98° Fh.) rather than increased, and this is often markedly the case towards the close of the disease, though then it has been noted as high as 100.8° Fh.

From the above sketch it is plain that the two most prominent factors in the disease, as presented during life, are—

- 1st. General weakness and anæmia.
- 2nd. Abnormal deposit of pigment in various parts of the body.

1. To the former of these is to be referred (a) the loss of muscular power, as evidenced by diminished muscular energy and force both in the voluntary and involuntary muscles, for the heart's action is feeble and imperfect, and the bowels are usually confined (b) At once a cause and consequence of the weakness and anæmia are loss of appetite, sickness and vomiting, though these, too, depend in part on other morbid changes, whilst, lastly (c), imperfect nutrition of the nervous system results, notably of the brain itself, whence arise vertigo, numbness, dimness of sight, deafness, tremors, and the like. The pain in the epigastric and hypochondriac regions is probably due to local causes.

2. The deposit of pigment is peculiar and characteristic. It is not uniform in disposition, and varies greatly in tint. It may only amount to a light brown or smoky discolouration in certain parts, or it may assume the appearance of a dark olive-green hue, approaching to black in some situations, especially over the genitals and nipples. Elsewhere it is most abundant on the face, where it often seems to begin, on the neck, the backs of the hands, the folds of the legs, and along either side of the linea alba. A striking peculiarity is that the conjunctivæ are clear and pearly, and that the nails are never discoloured. On the other hand, there is a great tendency to the deposit of pigment where the skin has been irritated or the epidermis removed, as by a mustard plaster or blister; but the skin is always smooth and supple. In a typical case under the writer's care, blisters had been applied to the chest for the uneasy feeling experienced there, and here the pigmentary tint was deeper than in any other part of the body, save the genitals. Cicatrixes affect the whole

depth of the skin do not seem to be so pigmented. The mucous membrane of the mouth not unfrequently becomes the site of pigmentary deposits. These are not diffuse, but, when the lips are affected, they usually take the shape of masses or lines. On the insides of the cheeks blotches or irregularly-defined spots are most common, as well as on the sides and root of the tongue. The latter spots are commonly better defined than are the others, and somewhat resemble the small well-marked black spots occasionally observed in parts already pigmented.

The site of this pigmentary deposit is in the growing layer of the epidermis, the usual site of colour in all races of mankind, and which is usually known as the *rete mucosum*; but occasionally pigmentary granules are to be found deeper, in the cells of the true skin.

An interesting clinical fact has been brought out by Dr. Greenhow, which will, probably, be noted in a considerable proportion of cases. This is the mode in which the disease progresses. Often it presents periods of remission, only to be followed by a more marked advance; but, notwithstanding these remissions, the progress is invariably towards a fatal termination. The time occupied in this progress varies much; it may be weeks or months, or it may be years, but in all well-defined cases the result is the same.

PATHOLOGY.—From the earliest description of the morbid state known as Addison's disease the malady has been associated with disease of the supra-renal capsules. At first it was supposed that any form of disease affecting these organs must give rise to a similar train of symptoms, and some of the investigations carried on with a view to sustain this position sound absurd enough by the light of subsequent experience. Gradually it has been made clear that only one kind of lesion is accompanied by the specific symptoms just detailed. Briefly, the morbid changes are as follow:—

Normally, the supra-renal capsules consist of two parts, a cortical and medullary, differing greatly in their structure. In Addison's disease both are superseded by a new structure, which is to be seen in various stages. In the earliest of these the capsules are invaded by a kind of translucent material, which is sometimes almost cartilaginous in its hardness, and which, when examined under the microscope, resolves itself into a kind of very finely fibrillar or trabecular connective tissue, with corpuscles like leucocytes freely congregated in the interspaces of the meshwork or between the fibres. This material, when seen in bulk, is grey or greenish-grey, afterwards becoming red on exposure. With it is mixed up an opaque yellow substance, varying in amount and apparently more abundant the more advanced the disease. In the earlier stages it presents the appearance of nodules embedded in the translucent material, but later almost the whole of this last may have disappeared, and the yellow opaque matter become converted into a thick creamy fluid, a putty-like substance, or even one or more caseous masses. This opaque material, then, is evidently, from its first appearance,

indicative of fatty degeneration, and closely resembles in every respect what used to be known as yellow or crude tubercle.

The exterior of the capsules presents certain important features. The capsules themselves may be large or small, according to the stage of the disease and the nature of their contents, but, even when they are small, it may be safely assumed that at one time they were enlarged. In all cases they will be found closely and strongly adherent to neighbouring structures. Some of these structures are of great importance, for example, the semi-lunar ganglia, and the vast plexus of nerves associated therewith, in which important changes have been found. These pathological conditions have been so often observed and so carefully noted, that they cannot be looked upon as accidental concomitants of the diseased process, but rather part and parcel of it, and, in all probability, as giving a clue to some of the most marked phenomena of the malady. Broadly it may be said that these changes consist in a great thickening of the connective tissue surrounding the nerve-fibres and the ganglion-cells, giving rise to something like compression and ultimate destruction of the nerve cells and fibres. This occurs both in the cerebro-spinal nerve fibres and in those more intimately connected with the ganglionic system. The nerve-cells, moreover, are not unfrequently deeply pigmented.

These, so far as is known, constitute the main pathological elements of Addison's disease. It does not arise from mere destruction of the supra-renal capsules, for then it would be seen under other conditions, as when cancer of a neighbouring organ extends to and involves the supra-renals, but no Addison's disease follows this event. The exact mode in which these nerve lesions give rise to the characteristic symptoms of the disease are, as yet, matters of speculation and not of exact science; and it may be said that our knowledge of the whole of this subject is yet in its infancy.

Though these are the main facts relating to the pathology of Addison's disease, there are still others of some importance. Pigmentation has been sufficiently noticed, but its origin has not been ascertained. Without doubt the pigment, like other animal pigments, is derived from the blood, and this has been examined with a view to discover any change in its composition which would explain the darkening of the skin, but without result.

In making the section of the body of one who has been the subject of Addison's disease, one cannot help being struck with the amount of subcutaneous fat, especially over the abdomen, as contrasted with the difficulties of nutrition under which the patient suffered, yet a considerable quantity is almost always found. But more closely connected with this malnutrition are certain changes in the absorbent system along the digestive tract. These consist in enlargement of the solitary and agglomerated glands constituting Peyer's patches, and of the mesenteric glands; as well as of lymphoid deposits in the mucous membrane of the stomach which give rise to little projections, termed *swammillations*, on the walls of that organ, especially,

near the pylorus. Small oedynoses are also not unusually found in the same situation. Of other organs it may be noted that the liver and spleen are often enlarged and hyperæmic, and the heart small and light.

DIAGNOSIS.—There would have been less difficulty or doubt in the diagnosis of Addison's disease, had it been clearly enunciated from the first that a bronzed skin did not alone constitute the malady. The disease rests on a triad of basis—*general weakness, diseased suprarenal capsules, and bronzed skin*, the last being the least important of the three. There may be darkening of the skin from a great variety of causes, viz.: (a) exposure, and attacks of *verruca* (*morbus Reomus*, Greenhow: *Verrucae Kraunkel*, Vogt); (b) wasting diseases, as chronic phthisis; (c) syphilis; (d) malaria; (e) liver disease or jaundice if long-continued, &c.; but in none of these cases should there be any difficulty if the preceding dictum is borne in mind.

PROGNOSIS—This is always unfavourable but it is impossible to assign any definite period for the termination of the disease, since it often progresses irregularly, with periods of improvement followed by relapse.

TREATMENT—From what has just been said it is plain that not much is to be effected by treatment as regards the cure of the disease, but much may be done by careful management to retard its progress and comfort the patient. As soon as the disease is discovered, the sooner the patient makes up his mind to an invalid life the better. Rest and careful dieting are the basis of the treatment. As regards diet, it may be briefly said that what the patient can take best suits best. As the stomach is so irritable anything likely to upset it should be avoided. Hence, as a rule, it is better to give concentrated nourishment, as essence of meat (*not the extract*) of chicken, or raw pounded meat, when other things cannot be taken. It is also important to bear in mind that the stomach will often tolerate food cold or even frozen, when hot substances would be promptly rejected. In certain stages of this malady it may well be said that the physician's success will depend more on his knowledge of the cookery book than of the Pharmacopœia—not, however, that our pharmaceutical gifts are to be despised. For the profound depression stimulants will be necessary, but these may take the shape of ether or spirits of chloroform, as well as of wine or brandy. For the irritable stomach, alkalies, with nuxvomica and meacuan, or columba, are of great service. So, too, in another way, are light tonics and neutral salts of iron; but the stomach should not be clogged with too much medicine. The bowels should not be much disturbed, but, if an aperient be required, a mild one, as a small dose of castor oil, or the compound liquorice powder of the Prussian Pharmacopœia will suit, if the stomach does not rebel; if so, a wineglassful of Hunyadi János water the first thing in the morning, followed by a cup of warm milk, may better agree with the irritable organ; when there is diarrhoea, a totally different line of treatment will be necessary. But in all

things, and at all times, the grand rule is to save the patient's strength, to add to it if possible, and to resist the inroads of the disease, whatever shape these may assume.

ALEXANDER SILVER.

ADENALGIA (ἀδην, a gland, and ἄλγος, pain).—Pain in a gland.

ADENTITIS—Inflammation of a gland. See the several glands.

ADENOCELE (ἀδην, a gland, and κύημα, a tumour).—A tumour connected with a gland.

ADENODYNIA (ἀδην, a gland, and δύνω, pain).—Pain in a gland.

ADENOID (ἀδην, a gland, and εἶδος, form).—(glandular; resembling the structure of a gland, whether secreting or lymphatic.

ADENOMA (ἀδην, a gland, and ὄμα, like).—A morbid growth, the structure of which is of glandular nature. See TUMOURS.

ADHERENT. ADHESIONS. }—Structures are said to be *adherent* when they become abnormally united together, the morbid formations by which this union is effected being termed *adhesions*. These are most frequently met with in connection with serous surfaces, being usually the result of an inflammatory process, but they may be observed in other structures. The adhesions vary considerably in extent, number, mode of arrangement, firmness, and other characters; they may merely consist of a few loose, slender, and delicate bands, or these bands may be thick and strong, or the contiguous surfaces may be blended and matted together to a greater or less extent, so that they cannot be separated without tearing or cutting them asunder, this last condition constituting *agglutination*. In structure adhesions consist mainly of connective or fibrous tissue, more or less perfectly developed, with a few new vessels.

EFFECTS.—Adhesions are often found at *post-mortem* examinations, which have been of little or no consequence during life, as, for instance, many of those which form in connection with the pleural surfaces. If, however, they are extensive and firm, or if they occupy certain regions of the body, they may prove of serious moment. The principal evils which are liable to result from adhesions may be thus indicated:—1. They often bind parts together, and interfere with the movements of important organs, such as the lungs, heart, stomach, or intestines; in this way preventing the due performance of their functions. 2. When an organ is displaced in any way, as, for example, the heart by pleuritic effusion, it may become fixed in its new position by the formation of adhesions, its functions being thus disturbed. 3. It is highly probable that agglutination may lead to hypertrophy of an organ, e.g., the heart, by overhauling its movements, and hence affecting its action. 4. On the other hand, atrophy or degeneration of structure may ensue, in consequence of the adhesions interfering with the due supply of blood by pressing upon the vessels, so that the nutrition of the tissues becomes impaired. In the young, also,

the development of structures may be checked. 6. Adhesions may involve important structures, such as nerves or vessels, pressing upon or destroying them, thus giving rise to symptoms of a serious nature. 6. Tubes or canals for the passage of secretions or other materials are sometimes narrowed or obliterated by adhesions. 7. When formed within the abdominal cavity, especially when they take the form of bands, adhesions may prove highly dangerous by compressing, constricting, exerting traction upon, or strangulating some portion of the intestine, in either of these ways leading to intestinal obstruction.

It is frequently difficult or impossible to determine the existence of adhesions by clinical investigation during life; but the history of some past illness during which they were likely to be formed, the results of physical examination, especially in connection with the heart and lungs, and the symptoms present, not uncommonly enable them to be discovered.

FREDERICK T. ROBERTS.

ADIPOCERE (*adeps*, fat, and *cera*, wax) — **СЛОВО:** Fr. *Adipocere*; Ger. *Fettwachs*.

DEFINITION.—A substance formed by a spontaneous change in the dead tissues of animals.

DESCRIPTION.—As seen generally in a dried state in museums, adipocere somewhat resembles spermaceti in consistence, but it is less crystalline in fracture, and is of a dull white or buff colour, the surface being marked by the outlines of blood-vessels or other textures. Adipocere in the earlier stages of its formation, or when formed in a damp situation, is soft, and if rubbed between the fingers communicates a greasy feeling. The odour is peculiar and rather disagreeable.

CHEMICAL COMPOSITION.—Adipocere dissolves in ether, leaving a delicate filamentous web; it burns with a blue flame, yielding a white ash. It is properly described as a soap composed of margaric and oleic acids in combination with ammonia, the fixed alkalies, and alkaline earths, the relative proportion of the latter ingredients varying with the age of the specimen (the ammonia disappearing), and with the composition of the fluids in contact with which the adipocere had been formed. It is said that oleic acid predominates in adipocere formed from dead fish.

MICROSCOPIC APPEARANCES.—When the flesh of animals in which this transformation has recently commenced is examined with the microscope, it is found to be composed of broken-down or disintegrated tissues, fatty granules or particles, together with a few acicular scales or crystals. The granules may be seen in what was muscular tissue to assume somewhat the arrangement of the muscular filaments, thus presenting an appearance resembling an early stage of fatty degeneration. In old and dry specimens of adipocere the crystalline scales form the greater portion of the mass, and they may be observed preserving the outlines of the muscular fibres.

ODOUR.—Adipocere has long been known. It is formed readily from the flesh of animals exposed to moisture, or placed in running water, in very dilute nitric acid, or in alcohol and water in the proportion of 1 to 6. It is often met with in inconvenient abundance in the

specimen jars of the anatomist. The bodies of men and other animals buried in peat moss have frequently been found completely converted into adipocere. Lord Bacon mentions it in the *Sylva Sylvarum*, and so also does Sir Thomas Brown in the *Hydrotophia*; but attention was especially called to its presence when a vast number of bodies were removed (in 1786-87) from the *Cimetière des Innocents* at Paris to the Catacombs. Fourcroy found many of these bodies converted into what he named *adipocere*, a name since retained. Gibbes (as did others) suggested the possibility of applying adipocere formed from the waste flesh of animals to some useful purpose, but the tenacity of the disagreeable odour and the presence of other difficulties have prevented these suggestions from being carried out. With respect to the immediate changes which give origin to adipocere chemists have differed in opinion. One class believes with Gay-Lussac and Berzelius that the compound results from the fat originally present in the tissues, and that the other components are completely destroyed by putrefaction. The other class, which includes the names of Thomas Thomson and Brande, maintains 'that the fatty matter is an actual product of the decay, and not merely an eluct or residue.' These opinions may, the present writer thinks, be reconciled by the better knowledge we now possess of the elementary composition of tissues. We know that the combination of fat and albumin constituting one of the earliest steps in the process of nutrition is traceable in the further development and formation of nearly every texture. When that combination is destroyed by a cessation of the process of life, the tissues are as it were resolved into their primary elements. We may thus have adipocere derived not only from free fat, but from the elements of fat existing in and obtained from the decomposition of other tissues. Adipocere may thus be described as both an eluct and a product. This opinion is confirmed by the researches of Bauer and Voit, who showed that fatty matter was derived from the metamorphosis of albumin in starved animals, to which phosphorus had been administered.

The interest concerning this substance is not confined to the chemist. The medical jurist has studied it with the view of determining the time and progress of its formation, and of thus ascertaining the probable period at which death occurred. But hitherto no decided or satisfactory information has been obtained, owing to the varied circumstances which influence the progress of the change in connexion not only with the condition of the body itself, but also with the character of its surroundings. The formation of adipocere has a further and a special interest for the pathologist. It was the study of this process which led the present writer to point out the analogy which exists between it and fatty degeneration in the living body, and thus to establish the pathological doctrine that fatty degeneration is the result of a retrograde metamor-

* The writer would desire to refer here to the analogy which seems to exist between the change of animal matter into adipocere, and that which occurs in vegetable matter by its conversion into peat and coal. This, however, is not the place in which to examine further such an analogy.

phobia, due to defective nutrition. (*See Medical and Surgical Transactions*, vol. xxxiii.)

RICHARD QUAIN, M.D.

ADIPOSIS.—A term which properly signifies either general corpulency, or accumulation of adipose tissue in or upon an organ. *See FATTY GROWTH*, and *OBESITY*.

ADYNAMIA } (à priv., and *dynamis*,
ADYNAMIC } power).—Terms indicating serious depression of the vital powers, and employed as synonymous with the *typhoid condition*. The adjective is applied to diseases in which the phenomena of this condition are prominent. *See TYPHOID CONDITION*.

ÆGOPHONY (ἀἴ a goat, and *phōnē*, voice).—A peculiar alteration of the resonance of the voice, as heard on auscultation of the chest, compared to the bleating of a goat. *See PHYSICAL EXAMINATION*.

ÆTIOLOGY (αἰτία cause, and *lōgos*, word).—That branch of pathological science which deals with the causation of disease. *See DISEASE*, Causes of.

AFFINITY.—This term is the designation of a property by which elementary and compound substances unite with one another and form new compounds. It is, therefore, a property with which chemists are principally concerned. But the ideas suggested to the chemist by the term affinity are also though less explicitly, excited in the mind of the pathologist and of the therapist by certain classes of facts frequently falling under their observation. The pathologist, for instance, knows that saline or earthy matter is very prone to accumulate in the midst of degenerated tissue in the walls of an artery or of a cardiac valve, so as to give rise to a patch of 'calcification'; he knows that in a gouty patient uric acid is most apt to accumulate and form 'chalk stones' in the tissue around affected joints, he knows that, however it may be administered, arsenic in poisonous doses tends to produce inflammation of the alimentary canal, that strychnia acts with preference upon the nervous system, and that in ordinary cases of lead-poisoning this metal interferes especially with the nutrition of the extensor muscles of the forearm. Applications of the same notion in the department of therapeutics are equally familiar in respect to the action of many drugs. It may be regarded as an ascertained fact that iodide of potassium tends especially to influence the nutrition of the fibrous structures in the body, and that bromide of potassium has a no less certain action in modifying the nutrition of the nervous centres in many unhealthy states. Again, there is a whole class of substances which when taken into the system have, whatever their other actions may be, an undoubted effect in modifying the functional activity of the kidney. We have in nitrite of amyl a remedy possessing a remarkable influence over the unstriated muscular fibres of the arteries and bronchi, or else over the nerve-centres by which they are controlled. We have in woorara an agent which acts especially upon the motor side of the ner-

vous system; and we have in digitalis an important remedy which, amidst its other effects, seems to have a decided power of improving the nutrition of the cardiac ganglia. The recent progress of therapeutics encourages us to hope that more and more of these specific effects of drugs will be accurately determined, so that the notion implied by the term *affinity* may, after a time, have a deeper meaning than at present for the practitioner of medicine. *See ANTAGONISM*.
H. CHARLTON BASTIAN.

AFFUSION.—A method of treatment which consists in pouring a fluid, usually water, either cold or warm, upon the patient. *See WATER*, Therapeutics of, and *BATHS*.

AFRICA, South.—*See APPENDIX*.

AGEUSTIA (ἀ, priv., and *gustis*, taste).—
Loss of taste. *See TASTE*, Disorders of.

AGONY (ἀγών, strife or struggle).—Agony implies bodily pain or mental suffering so intense that it cannot be endured, but excites a struggle against it. It is also applied to the final struggle that often precedes death. *See DEATH*, Modes of.

AGORAPHOBIA (ἀγορά, a market-place, and *phobos*, fear) *SYNON.* Fr. *La peur d'un espace*.—By these names a peculiar nervous complaint has been recognized, characterised by a feeling of alarm and terror, accompanied with a group of nervous symptoms, which some individuals experience when they are in a certain space. The condition may be developed rapidly or gradually, and the chief phenomena observed are as follows:—A sudden sensation is experienced, as if the heart were being grasped, while this organ palpitates violently, the face becomes flushed, the legs feel weak, tremble, and seem as if they would give way under the body. There may be sensations of itching, coldness, or numbness, or profuse sweating may occur. There is no true vertigo; the special senses are unaffected; and consciousness is not at all impaired. A curious impression is sometimes experienced, as if space were elongating itself out indefinitely. Persons who are thus affected are quite sensible of the foolishness of their fear, but cannot be reasoned out of it. During the attacks they feel a strong inclination to cry out, but fear to do so. They think that their dread is known to others, and many of them endeavour to conceal their feelings, lest they should be considered insane.

The circumstances under which the symptoms just described may be experienced are various. They may be felt, for instance, in the street, especially if the shops are shut; in public buildings, such as churches, concert-rooms, or theatres; in omnibuses, cabs, or other conveyances; on a bridge; or in looking at an extended façade or flying perspective. Most persons who suffer thus in the street feel better when with some one, or when near some object, such as a carriage, or even when carrying an umbrella or a stick. Occasionally, however, they shun other people, especially acquaintances.

But little is known as to the origin and nature of agoraphobia. The complaint is not regarded

as idiosyncratic, but as sequential to some other condition. It occurs in males and females, and the individuals affected may be strong and in good bodily health, while they are often intelligent and well-educated. A history of hereditary nervous disorder can be traced in some cases, indicated by the occurrence of insanity or epilepsy in members of the family; and the patients themselves may present indications of a nervous temperament. Their emotions may be easily excited; and they may be subject to nervous symptoms, such as headache, a feeling of heat in the top of the head, sparks before the eyes, occasional faintness, or motor disorders.

AGUE-CAKE—A form of enlargement of the spleen, resulting from the action of malaria on the system. See SPLEEN, Diseases of, and MALARIA.

AIR, *Ætiology of.* See DISEASE, Causes of.

AIR, Therapeutics of.—Air is employed in the treatment of disease in many ways and for many purposes. It is used, first, as the *atmosphere*, a gaseous mixture of definite composition and with a variable pressure. Secondly, advantage is taken of air as a *vehicle* for other substances in the gaseous or finely divided state. And, thirdly, it is selected as a *medium* by which the *temperature* of the body may be readily and effectively influenced. In the first of these relations only—as pure air—will its therapeutics require to be considered in this article. The application to the body generally of air that has been warmed, or warmed and loaded with moisture, will be found described in the article on *BATHS*; while its administration to the respiratory organs, either in this form or as a vehicle for such substances as creosote, carbolic acid, alkaloids, and sulphurous acid, will be discussed under *INHALATIONS*.

PRINCIPLES.—The dual relation in which the air stands to the economy—as a definite compound of certain gases, and as an atmosphere with a certain pressure—is very frequently disturbed; and this disturbance accounts for some of the most familiar phenomena of disease. Alteration in the quality or quantity of the respired air, whether from the state of the atmosphere itself or from derangement of the complex apparatus of respiration and circulation, is the cause of some of the most serious and distressing symptoms attending diseases of the chest. It might be predicted by the physiologist that under those circumstances relief would be afforded, at least to symptoms, by suitable alteration of the composition or volume of the air. The margin of

treatment thus rationally indicated is further readily practicable—the supply of air is unlimited; its composition may be altered at pleasure, its pressure may be increased or diminished, and such alteration will alter its chemical properties. We find accordingly that, ever since the discovery of the composition of the atmosphere, frequent trials have been made of its value therapeutically. Oxygen was early recognised as its active constituent, and came to be administered, as it still is, in the form of inhalation. From time immemorial, indeed, advantage has been taken of the purity and certain other unknown qualities of the air for the prevention and treatment of disease, and the character of the atmosphere is naturally reckoned one of the most important elements of climate (*see CLIMATE*). More recently use has been made of the powerful properties that air possesses when *physically* changed. Within the last few years a remarkable advance has been made, on the one hand, in the physiology of respiration and the relation of the circulation to the atmospheric pressure, and, on the other, in the pathology of diseases of the chest. Clearer views have been reached on the significance of various symptoms, and especially of dyspnea in its different forms. At the same time observations upon the effects of compressed and rarified air have been becoming more exact. Pursuing the physiological track, modern therapeutists have availed themselves of this knowledge, and revived the use of air physically altered in the treatment of diseases of the lungs, heart, and other parts of the body. This application they are now able to make with accuracy, and the success of the reformed system of *aërotherapeutics* appears to be unquestionable. Although in England it is seldom heard of beyond hydropathic establishments, the system is more extensively employed on the Continent. Its leading principles and some of its most important applications will be here briefly described.

The physiological effects of compressed or of rarified air will manifestly be different according as it is admitted to the body as a whole, or only to a part of it. Familiar examples of the former condition are afforded by descent in the diving-bell, or ascent in the balloon; and of the latter by the action of the cupping-glass and the effect of interrupted or frequently repeated respirations upon the pulse and system generally. Under the first circumstances the alteration of pressure is absolute; under the second it is relative, and capable of producing most important disturbances in the distribution of the vital fluids. The two methods of application must accordingly be separately discussed.

GENERAL AËROTHERAPEUTICS.—The effects of compressed air on the body as a whole have been studied in the *air-bath*, a simple mechanical arrangement in the form of an iron chamber, which can be filled with air at any pressure, whether above or below the normal, by means of steam-power. The principal physiological effects of air condensed by three-sevenths of an atmosphere were ascertained by von Vivenot to be—Pallor of the skin and mucous membranes; a sensation of pressure in the ears;

diminished frequency of respiration, the act becoming easier; enlargement of the lungs, and increase of the vital capacity; depression of the cardiac force, and diminution of the size and strength of the pulse; rise of temperature; increased rigour of muscular action, secretion, and nutrition generally; compression of the gaseous contents of the intestines; and, perhaps, increased absorption of oxygen and excretion of carbonic acid. When the pressure is excessive, dangerous or even fatal symptoms may supervene. Frequent exposure to condensed air will induce considerable increase of the vital capacity; and most of the other effects, both physical and chemical, will tend to persist. In a word, it may probably be said that the air-bath acts on the system, first, by increasing the general mechanical pressure; and secondly, by admitting an increased amount of oxygen. In employing the air-bath, the patient is kept in it for a period of two hours, at first daily, but after some weeks less frequently. The pressure, which is employed in different cases at one-fifth to one-half of an atmosphere above the normal, must be slowly raised on admission, and reduced on removal of the patient.

The number of *diseases* in which the air-bath may be given with success is limited:—(1.) In certain forms of dyspnoea—thus it gives great relief in spasmodic asthma, and may also afford temporary relief in emphysema, but its prolonged use appears to be positive ly bad, as it increases the pulmonary distension. (2.) In hyperæmia and catarrh of the air-passages, including pertussis. (3.) In imperfect expansion or threatened retraction of the chest, as in the subjects of phthisis and chronic pleurisy. Compressed air has also been extolled in some forms of cardiac disease, and in general malnutrition.

The effects of *rarefied air* admitted to the body as a whole do not demand description in this place, either in their physiological or in their therapeutical aspect. Artificially rarefied air is never employed in the form of the bath, and the natural supply in elevated regions, which has found so much favour as a means of treatment in phthisis, is a subject that belongs to CLIMATE and PHTHISIS.

LOCAL ALIOTHERAPEUTICS.—When it is desired to bring compressed or rarefied air into contact with the *respiratory surface* only, a different apparatus must be employed. Several forms have been introduced, respecting which it will be sufficient to state that the air contained in a gas-holder is compressed or rarefied by simple mechanical means, and thereafter brought into relation with the air-passages by an arrangement of tubes and valves. There are four possible methods of application:—(1.) Inspiration of condensed air; (2.) Expiration into condensed air; (3.) Inspiration of rarefied air; and (4.) Expiration into rarefied air. The physiological effects of the several methods have been carefully investigated by Professor Waldenburg, of Berlin, whose account we shall follow.

Inspiration of condensed air.—Inspiration of air that has been condensed by one-sixtieth to one-fortieth of an atmosphere produces a sensation of extreme distension of the chest, accompanied by an actual expansion

of the thorax and lungs, and an increased admission of air, so that inspiratory dyspnoea, if present, is relieved. At the same time the other thoracic contents are compressed, the systemic vessels fill, the arterial pressure rises, and the jugulars become distended. The lungs and heart will be comparatively anæmic. If the application of condensed air be frequently repeated, the vital capacity, the size of the chest, and the respiratory force, may all be increased, and partial relief may be permanently afforded to dyspnoea.

Expiration into condensed air is most difficult of accomplishment, and ends in apnoea in inspiratory time. The effect on the circulation does not differ essentially from that just described.

Inspiration of rarefied air.—Inspiration of air that has been rarefied by one two-hundred-and-fortieth to one one-hundred-and-twentieth—or even, after a time, by one-sixtieth—of an atmosphere, immediately causes the phenomena of inspiratory dyspnoea: the thoracic viscera are congested, and hæmoptysis may result, for the effect may be regarded as that of dry-cupping the pulmonary alveoli. The heart at the same time becomes full, and the jugulars collapse.

Expiration into air that has been rarefied by one-sixtieth of an atmosphere is attended with a sense of extreme compression of the thorax; at the same time there is actually a partial retraction of the lungs, an increase in the volume of expired air, and a corresponding diminution in the amount of residual air in the chest. Expiratory dyspnoea, if present, is relieved. While the lungs thus diminish in size, the other thoracic viscera are dilated—the heart and the pulmonary and other vessels within the chest being filled at the expense of those external to it, both arteries and veins. If the expiration into rarefied air be frequently repeated, the circumference of the chest will be diminished, while the vital capacity will be actually increased, along with increase of the inspiratory and expiratory force.

Applications.—The method of *inspiring condensed air* is obviously indicated in diseases where inspiratory dyspnoea is an urgent symptom. Spasmodic asthma, stenosis of the air-passages from anatomical causes, acute and chronic bronchitis, and atelectasis, have all been successfully treated by this method. In croup, where it is urgently indicated, it is most difficult or even impossible to employ. In threatened phthisis it is used prophylactically; and in chronic pleurisy it may prevent or remove the effects of collapse and retraction of the chest wall. The inhalation of condensed air should also be of use in certain forms of cardiac dilatation, especially that due to mitral incompetence. Improving as it does the general nutrition, it may be combined with other remedies for anæmia. In the administration of condensed air, a 'sitting' should last from ten to thirty minutes, once a day—seldom twice.—**Expiration into condensed air** is not used therapeutically.—**Inspiration of rarefied air** may be regarded as a means of exercising the inspiratory muscles. Like the atmosphere of great altitudes, it may therefore be employed in persons with badly developed chests; and even in phthisis it may, by increasing the amount of blood in the lungs, prevent cavitation and promote absorption of the

products. In disease of the right side of the heart, it would assist the flow of blood from the veins into the lungs, but it is not likely to be employed for this purpose.—*Expiration into rarefied air* promises to be the most successful and most extensively employed of all the methods. In it, according to Waldenburg, we have the physical antidote for emphysema, and in his hands the majority of such patients have been either cured or radically benefited. It has also afforded great relief in some cases of bronchitis, where it increases expectoration.

Other local applications of the physical properties of the air, as seen in aspiration, cupping, Junod's boot, and inflation, are described elsewhere in this volume. J. MITCHELL BRUCE.

ALBINISM (*albus*, white)—DEFINITION.—A state of whiteness or absence of colour of the integument and certain other tissues, consequent on defect of pigment-formation. The want of colour may be complete or incomplete, partial or universal; congenital or accidental. Partial albinism may be limited to a spot of small dimensions; or there may be many such spots of variable extent, dispersed over the surface of the body, and giving rise to the appearance which is denominated *pied* or *piebald*, whereas in universal albinism the defect of pigment is not restricted to the integument, but is especially remarkable in the iris and choroid membrane of the eyeball.

GENERAL CHARACTERS.—Persons and animals affected with albinism are called *albinoes*. It would seem more correct to limit the term *albino* to those in whom the absence or defect of pigment is universal, and demonstrable not only in the integument but likewise in the eyeball. In the true albino, therefore, the skin is white and pink and more or less transparent, and this both in the fairer and in the darker races of mankind; but in certain of the latter, where the pigmentary function is simply defective and not totally wanting, the colour of the skin may be grey or tawny, and more or less variegated and freckled. The hair, sometimes of a pure silvery or opaque white, may be diversely tinged with yellow or red; occasionally it is flaxen or possesses a greyish hue; and in some instances the whole body is covered with a white down. The iris is grey or pink in accordance with the density of its fibrous structure, and the consequent facility of penetration of the colour of its vascular layer; or, as generally happens in the negro, it is blue. The pupil is contracted and brightly red from the absence

of the screen of protection usually afforded to the choroid membrane by its pigmentary layer; and for the same reason the rays of light penetrating the sclerotic and iris give a brilliancy of appearance to the fundus of the eyeball. The absence of pigment in the eyeball is productive of several peculiarities of character in the albino. In the first place the excess of luminous rays penetrating the coats of the eyeball interferes with the correctness of his vision; his retina is intolerant of light, he stoops his head, or droops his eyelids, to shelter his eyes; he sees with more comfort in the dimness of evening than in the light of the sun; he is near-sighted; and there is in many cases an oscillation of the eyeballs.

ÆTIOLOGY.—Albinism is met with among all races of mankind and in every country, but is most common amongst those who are subjected to insalubrious conditions of climate and hygiene. For these reasons it is not uncommon among the natives of the marshy coast of Africa; among negroes who are transferred to unhealthy districts in South America and the West Indies; among the inhabitants of the western coast of South America and Mexico, in certain of the islands of the Indian Ocean; and even in the northern regions of Europe. When albinism is congenital, it has been assumed to be due to an arrest of development; but when accidental, its existence must be referred to exhaustion of chromatogenous or pigment producing function. Arrest of development has been inferred from the occasional persistence in albinoes of the membrana pupillaris, and of the fetal down of the skin; from the more frequent occurrence of the condition in females than in males; and from the observation that albinoes are sometimes misshapen and feeble intellectually as well as physically. On the other hand it is well known that albinism is often associated with perfect physical strength and remarkable intellectual vigour. Among other causes to which it has been assigned are heredity, and debility, however induced.

TREATMENT.—The treatment of congenital albinism must consist in the application of those agencies which tend to strengthen and improve the general health. With regard to the special inconvenience resulting from the absence of pigment in the eyes it has been observed that the difficulty felt in reading is greatly lessened by using screens or goggles made of some opaque material, such as aluminum, such perforated by a small opening, admitting only the rays of light from the object looked at. The treatment of accidental albinism will be considered under PROMPTARY SKIN-DISEASE. ERASMUS WILSON.

ALBUMINOID DISEASE—SYNON.: *Waxy*, *Lardaceous*, and *Amyloid Degeneration*, Fr. *Dégénération amyloïde*. Ger. *Speckartige Degeneration* (Rokitansky); *Amylunde Entartung* (Virchow).

DEFINITION.—A peculiar form of degeneration, affecting certain organs, and constituting in its effects a distinct and general disease.

ÆTIOLOGY.—In the majority of cases albuminoid disease is preceded by long-continued suppuration, most frequently in the form of bone- or joint-disease; or else of destructive pulmonary phthisis, empyema, pyelitis, cystitis,

and other affections, where there has been a constant drain of pus. In the absence of obvious suppuration, there is usually present an exhausting disease, as syphilis, ague, or some more obscure cachexia. These antecedent conditions must be regarded as the cause of the malady, and it is only in the rarest instances that no such cause can be traced. It is not easy to recognise the connection, but it may be pointed out that a drain of pus involves not only a loss of highly organised protoplasmic material, but also of potassium salts, which are contained in large proportions in the solid elements of pus, and which salts, as we have seen, are deficient in the affected tissues.

ANATOMICAL CHARACTERS.—The organs affected are usually much enlarged, but sometimes they ultimately decrease in size. They are pale, dense, dry, sometimes hard, and either generally or in certain spots translucent. In an advanced stage of the disease the parts appear as if soaked in wax, or other translucent material. If incised, in alcoholic or aqueous solution, be applied to the affected parts, they are stained yellow, orange, or a deep mahogany brown, according to the degree of the morbid change. If the portions thus coloured be further treated with dilute sulphuric acid, a purplish black colour is produced. These characters depend upon the presence in the tissue-elements of a peculiar substance, allied to the albuminates, and containing, when approximately pure, about 15 per cent. of nitrogen. It is soluble in alkalis, not digested by pepsine, and not readily altered by putrefaction, it gives with iodine the characteristic colour just noted, which gave rise to Virchow's erroneous supposition of its being allied to starch, whence the name—*Amyloid*. This *albuminoid* material being contained in the tissue-elements themselves, and not infiltrated between them, is probably not poured out by the vessels as such, but results from a transformation of the materials of the tissues. Chemical analysis of the affected organs shows a remarkable change in their mineral constituents, the potassium and phosphoric acid being very greatly diminished, as compared with healthy organs; while the sodium and chlorine remain normal, or are proportionately increased.

Albuminoid disease affects most frequently the liver, spleen, and kidneys. Next in order of frequency comes the lymphatic glands, and the intestinal mucous membrane, especially its villi, more rarely the suprarenal bodies, the pancreas, the urinary mucous membrane, or the omentum are involved; and quite exceptionally, other parts, such as the thyroid body, the generative organs, the heart, and the lungs. In most organs the blood-vessels and their appendages, (glomeruli of the kidneys, Malpighian corpuscles of the spleen) are the seat of the morbid change; but in some, such as the kidney, secreting cells may also be affected, and in the liver these structures are chiefly or solely involved. The diseased elements are enlarged, translucent, and structureless.

SYMPTOMS, DIAGNOSIS, AND PROGNOSIS.—The general symptoms of albuminoid disease are anemia, debility, a cachectic appearance, and sometimes capillary hæmorrhage. The local symptoms are chiefly important in the case of the liver, spleen, and kidneys. Uniform smooth

enlargement of the liver and spleen, which can be referred to no other cause, may be due to the albuminoid change. Where the kidney is affected, albuminuria, dropsy, uræmia, and a train of symptoms arise, which, regarded as a whole, differ from those of other kidney diseases. The *diagnosis* is greatly confirmed by (1) the simultaneous occurrence of disease in several organs; (2) a history of suppuration, or of some cachectic disease, especially syphilis. The *prognosis* is extremely unfavourable, and, when the disease is far advanced, it is hopeless.

TREATMENT.—Though in advanced cases treatment can avail but little, there is reason to think that were the occurrence of disease anticipated, or its presence earlier recognised, prevention, or even cure, might be possible. In all such complaints as chronic joint-disease, psoas abscess, syphilitic disease of bone, or prolonged empyema, the probability of this frequently fatal *sequela* should be borne in mind, and guarded against by a suitable regimen. The diet should not only be generally nutritious, but should include more especially abundance of nitrogenous food (albuminates), as well as the potassium salts, which the affected tissues lack. These are, indeed, largely contained in the juices of fresh meat, and also in the green parts of vegetables. Among drugs, nutrient tonics, of which iron and cod-liver oil are the type, must hold the first place; but the administration of potassium salts, as proposed by Dr. Dickinson, is also indicated. Of these we should be induced, on *a priori* grounds, to select those of which the local action is least violent, and which cause little vascular depression, such as the bicarbonate, or the citrate, or other organic salts. The danger of 'potash poisoning' is very remote.

J. F. PAYNE.

ALBUMINS.—**DEFINITION.**—Albumins are substances closely resembling egg-albumin, the chief constituent of white of egg or albumen. To distinguish between the white of egg and its chief constituent, the former is split albumen and the latter albumin. Albumins constitute a sub-division of the class of albuminous bodies, which includes all substances having a general resemblance to albumen.

ENUMERATION.—The sub-class properly contains only two members, *egg-albumin* and *serum-albumin*, but the name *Bence-Jones's albumin* has been given to an albuminous body differing very considerably in its properties from the other two.

CHARACTERS.—Egg-albumin and serum-albumin are semi-transparent, yellowish, and structureless when dried. They are soluble in water; and this solution is coagulated by boiling. From the same solution they are precipitated by (a) nitric acid; (b) salts of the heavy metals, for example, copper-sulphate; (c) acetic acid with potassium-ferrocyanide; (d) boiling with acetic acid and a neutral salt, for example, potassium-sulphate; (e) alcohol. Egg-albumin is distinguished from serum-albumin by the coagulum which it forms with nitric acid being insoluble in excess, while that of serum-albumin is soluble. Bence-Jones's albumin gives no precipitate with excess of nitric acid unless left to stand, even when heated and left to cool, when it forms a *coagulum*.

coagulum. This coagulum redissolves on heating, and again forms on cooling. It may be separated from ordinary albumin by adding nitric acid, boiling, and filtering when hot. The ordinary albumin will remain on the filter while Bence-Jones's albumin will pass through, and will coagulate when the filtrate cools.

MODIFICATIONS.—By the action of acids and alkalis albumin may be converted into *acid-albumin* and *alkali-albumin* respectively, neither of which is coagulated by boiling.

Acid-albumin may be formed in two ways:—First, by dissolving solid albumin in concentrated nitric or other mineral acid with the aid of heat. Secondly, by heating an aqueous solution of albumin with one of these acids very much diluted (1 in 500). Although soluble in very concentrated or very dilute acids, acid-albumin is insoluble in moderately dilute acids. Therefore, when the solution in concentrated nitric acid is diluted with water, a precipitate is formed, which redissolves when much water is added. And, conversely, when acid-albumin is made by boiling a solution of albumin in water with very dilute nitric acid, the addition of more acid will throw down a precipitate, which redissolves if a very large excess of the concentrated acid be added, and especially if it be heated at the same time. On neutralising a solution of acid-albumin, a precipitate is thrown down, which dissolves in excess of alkali.

Alkali-albumin, or *alkali-albuminate* as it is also called, is formed by dissolving albumin in caustic potash or soda; or by adding either of these to its aqueous solution and allowing this to stand, or heating it. This modification is not precipitated by heat, but is precipitated by neutralization; the precipitate dissolving very readily in slight excess of acid. If alkaline phosphates are present in the solution, as they are in urine, alkali-albumin requires a slight excess of acid to throw it down, and is not precipitated by exact neutralization, as acid-albumin would be under similar circumstances. T. LAUDER BRUNTON.

ALBUMINURIA.—**DEFINITION.**—A condition characterised by the presence of albumin in the urine. Other albuminous bodies, not albumins, may be present in hæmatinuria, hæmatæria, pyuria, and spermatorrhœa.

SYMPTOMS.—Albumin may occur in the urine without any symptoms whatever, but its continuous loss leads to anæmia and changes in the circulation, which usually originate the following symptoms—a pallid pasty complexion, dry skin, and tendency to œdema of the cellular tissue noticeable on the eyelids and shins; derangement of digestion, flatulence, occasional nausea, and irregularity of the bowels; nervous disorder shown by muscular weakness, languor, lassitude, vague pains about the loins, and headache; calls to make water during the night; palpitation, and frequently accentuation of the second sound of the heart over the aortic cartilage, and reduplication of the first sound over the septum ventriculorum.

TESTS FOR ALBUMIN.—The two tests usually employed to detect albumin in the urine are—first, boiling; and, secondly, the addition of nitric acid; both of which produce a cloud or precipi-

tate. If the urine is turbid the albuminous cloud may not be noticed; and therefore such urine should be filtered before the application of either test, unless the turbidity, being dependent on the presence of urates, is removed by heat.

Method of employing the test by boiling.—With the object of saving time the urine is often boiled at once, but the results thus obtained are liable to several fallacies, which will be subsequently described. In order to avoid such fallacies the following method should be pursued:—Ascertain the reaction of the urine; and, if it be alkaline or very strongly acid, add acetic acid in the one case, or liquor potassæ in the other until its reaction is only slightly acid. Fill a test-tube to about one-third of its capacity with the urine, and hold it obliquely in the flame of a spirit lamp in such a manner as to heat the upper part of the fluid only, until it boils. If it be turbid from urates, it should be first warmed throughout until it becomes clear, and then the upper part only should be boiled. Finally, add a drop or two of acetic or nitric acid.

If albumin be present, it will form a cloud or a coagulum, more or less dense according to its amount. When there is much albumin, its quantity may be roughly estimated by allowing the urine to stand for a definite number of hours, so that the coagulum may subside, and then observing whether it forms a fourth, a third, or a half of the whole length of urine in the test-tube. A small quantity causes a cloud, but no distinct coagulum; and, if merely a trace be present, a faint haze only will be observed, which is best seen by looking through the test-tube at a dark object. The advantage of heating the upper part only of the urine is, that the lower portion, which remains clear, affords a standard by comparison with which a faint cloud in the heated part may be more readily detected.

Fallacies of the test by boiling.—The first fallacy is that albumin may be present, and yet no cloud or coagulum be produced on boiling. This may occur if the urine be alkaline or very strongly acid, because alkali-albumin or acid-albumin, which are soluble in water, may be formed. It is to prevent the formation of *alkali-albumin* that acetic or nitric acid should be added to alkaline urine before boiling. This addition of acid also causes the coagulum to separate more readily; and it should therefore be made when the urine is neutral. On the other hand, urine rarely or never contains sufficient acid to form *acid-albumin*, unless the patient has been taking mineral acids; and therefore the addition of liquor potassæ is not necessary except under these circumstances. The second fallacy of the test by boiling is, that a cloud resembling that of albumin may be produced, although the urine is free from this substance. This occurs when the acidity of the urine is too slight to hold the earthy phosphates in solution, without the aid of the carbonic acid which it usually contains. When such urine is boiled, the carbonic acid is driven off, and the phosphates are precipitated, forming a cloud like that of albumin. The two clouds are readily distinguished by the addition of a drop or two of nitric or acetic acid, when if due to phosphates it will disappear

by solution; but if caused by albumin it will remain. If an excessive quantity of nitric acid be added, an albuminous cloud may also clear up; for albumin coagulated by heat is soluble in strong acid, though only to a slight extent.

Application of the nitric-acid test.—Pour some urine into a test-tube, and then allow about one-fourth of its bulk of strong colourless nitric acid to trickle slowly down the side of the tube, so as to form a layer below the urine without mixing. Or the acid may be put in the test-tube first, and the urine poured on it. Both processes give the same result. If albumin be present, a haze or cloud will form close to the line where the liquids meet.

Fallacies of the nitric-acid test.—1. Albumin may be present and yet escape detection, if the nitric acid is simply poured into the urine and mixed with it, as is sometimes done. For if there be too much or too little acid, acid-albumin is formed and dissolved; whereas, if the liquids form two distinct layers, as in the process already described, the acid gradually mixes with and shades off into the urine, so that, at a greater or less distance from the line where they join, it is certain to be of the proper strength to precipitate the albumin. 2. Albumin may be supposed to be present when it is not, from the formation of a cloud by the precipitation of acid urates or uric acid. This cloud disappears on the application of heat, and another specimen of the urine tested by boiling gives no cloud. To avoid this fallacy, it is common to employ the test by boiling, in addition to that by nitric acid. 3. The third fallacy is not of common occurrence. It is due to the presence of fat or saponified fats in the urine. Urine containing these when simply boiled gives no cloud; but if nitric acid is added to it in the cold, or acetic acid when it is hot, the fatty acids are precipitated and form a cloud resembling albumin. This is distinguished by not being formed if along with dilute acetic acid some ether is added to the urine before boiling; the ether retaining the fatty acids in solution. If the precipitate produced by nitric acid be collected on a filter, and treated with ether, it will be dissolved, while an albuminous precipitate will not. Copra, which can be recognised by its smell, sometimes causes an opalescence in the urine, which is increased by nitric acid, but is removed by heat.

Additional tests for albumin.—When urine contains mucus, which would render the presence of an albuminous cloud obscure, a solution of ferrocyanide of potassium followed by acetic acid should be added; this will produce a cloud if albumin be present, while it rather clears up a turbidity due to mucus. A solution of pyrophosphate of soda also precipitates albumin. If a drop of albuminous urine be poured into a test-tube containing one or two drachms of a saturated solution of picric acid, a precipitate is formed. These tests are sometimes useful in determining the presence of albumin in the urine in doubtful cases.

QUANTITATIVE ESTIMATION OF ALBUMIN.—There are three methods in common use for this purpose. The first is easy but inexact. It consists in boiling the urine with dilute acetic acid in a test-tube, allowing the coagulum to subside for

a definite number of hours, and then estimating the proportion it bears to the quantity of urine boiled, for example, a fourth, a third, &c. The second is the most exact, but is troublesome. It is like the first; but the urine is carefully measured before boiling, and the amount of coagulum is ascertained by collecting it on a weighed filter, washing, drying, and again weighing it. The third method is easy and tolerably exact. A tube of known length is filled with urine and placed in a polarizing apparatus. From the amount of rotation which the polarised ray undergoes in passing through the urine, the amount of albumin it contains may be calculated. A fourth method has recently been recommended by Dr. W. Roberts. It consists in diluting the urine with water until it gives a haze on the addition of nitric acid, which does not become visible until between one-half and three-quarters of a minute after the acid has been added. This dilute urine contains 0.0094 per cent. or 0.0148 grain of albumin per fluid ounce; and from the degree of dilution required the amount contained in the urine may be calculated.

PATHOLOGY.—Albuminuria has been said to occur in consequence of various conditions: e.g., changes in the blood, changes in the circulation, changes in the kidneys. Thus abstinence from salt, or a diet of eggs alone, is said to produce albuminuria by altering the constitution of the blood; and an alteration in this fluid is supposed to be partly the cause of the albuminuria observed in high fevers, scarlatina, diphtheria, and osteo-malacia. The albuminuria of heart-disease depends on changes in the circulation, and that of nephritis on alterations in the kidney. In order to distinguish more clearly between the different kinds of albuminuria we may divide them into—1st, *true albuminuria*, in which serum-albumin appears in the urine; 2ndly, *false albuminuria*, in which some other albuminous body, but not serum-albumin, is present. In *true albuminuria* there is always some change either in the circulation through the kidney, or in the structure of the kidney itself. In *false albuminuria* the albuminous body passes out through the kidney, without there being any alteration either in its circulation or structure.

The chief albuminous bodies occurring in *false albuminuria* are hæmoglobin, egg-albumin, and Bence-Jones's albumin. Hæmoglobin occurs in the urine whenever blood is present in it (see HÆMATURIA), in which case it is contained in the corpuscles; or it may occur free (see HÆMATINURIA), the blood-corpuscles, while still circulating in the vessels, having undergone solution. This may result from the inhalation of arseniuretted hydrogen, or from the introduction of bile-acids or of a large quantity of water into the veins. Hæmoglobin is also found in the urine in paroxysmal hæmatinuria, but the cause of the solution of blood-corpuscles in this disease is unknown. Egg-albumin is excreted by the kidneys, and appears in the urine, whenever it is injected directly into the circulation or under the skin, or when it is absorbed unchanged from the stomach or rectum. When taken into the stomach it is usually completely digested before it undergoes absorption; but when taken in such

large quantities that the whole of it cannot be digested, part of it is absorbed unchanged and is excreted in the urine. Thus a diet consisting exclusively of eggs, especially when continued for several days, produces false albuminuria, and large emaciated of eggs have a similar effect in animals and probably also in man. Bence-Jones's albumin is of very rare occurrence. It is found in osto-malacia. Like egg-albumin, it is excreted by the kidneys when it is injected into the circulation or in large quantities into the intestine. It is almost if not quite identical with the hemialbumose, which Kuhne finds to be one of the products of imperfect digestion. It seems probable that those cases of albuminuria which appear to depend on imperfect digestion are due to the passage into the systemic circulation of albuminous bodies, which have not undergone the proper transformation in the alimentary canal or liver.

In *true* albuminuria there must be some change, either in the circulation or structure of the kidney, for serum-albumin differs from the other albuminous bodies just mentioned, in not being excreted by the healthy kidney. Some regard the alterations in circulation which produce albuminuria as of two kinds:—(a) increased pressure of blood in the renal arteries; (b) increased pressure in the renal veins. Increased pressure in the arteries may depend either on general high arterial tension, or upon an increased local supply of blood to the kidney, owing to dilatation of the renal arteries, such as follows division of their vaso-motor nerves. Experiments seem to show, however, that increased tension in the renal arteries does not produce albuminuria, and that the only change in circulation which will cause it is increased pressure in the renal veins. Congestion of the renal veins may be produced by ligation of the renal arteries, and when the flow of blood through the kidney is temporarily arrested by ligation of the artery, the urine secreted after the removal of the ligation is albuminous. Venous congestion of the kidney also occurs whenever the onward flow of venous blood is obstructed, either by a ligation on the renal veins; by the pressure of a tumour or of the pregnant uterus upon them or the vena cava; by disease of the liver obstructing the vena cava; or by disease of the heart or lungs, such as tricuspid or mitral regurgitation, or chronic bronchitis and emphysema. The temporary albuminuria sometimes observed after cold bathing may also be due to venous congestion, and it is probable that albuminuria consequent upon lesions of the nervous system is due rather to the changes which these produce in the circulation than to any direct action of the nerves upon the tissues of the kidney itself. The albuminuria observed after varnishing the skin is probably due to the retention of some substance which acts as a poison. The structural changes in the kidney which cause albuminuria are acute and chronic inflammation, waxy degeneration, and cirrhosis. See Bence-Jones's Disease.

TREATMENT.—In *false* albuminuria where hæmoglobin appears in the urine, the treatment indicated is to counteract the solution of blood-corpuscles; and for this purpose quinine is very efficacious. When other kinds of albumin ap-

pear in the urine, and are probably due to imperfect digestion, the treatment is to give some artificial digestive fluid. Arsenic is also useful. Regarding those cases of osto-malacia in which Bence-Jones's albumin occurs, we unfortunately know very little.

In *true* albuminuria, depending on venous congestion, the obstacle to free circulation should be removed, if possible; and congestion lessened, both by drawing the blood from the interior to the surface of the body, and by causing contraction of the renal vessels. The blood may be drawn from the interior to the surface by means of warm baths, but in some cases they prove injurious rather than useful, and the employment of a wet pack, which has a similar effect on the distribution of blood without exciting the heart, is to be preferred. Cupping over the kidneys is serviceable: it probably acts by causing reflex contraction of the renal vessels rather than by actually draining blood away from them. The tone of the renal vessels may be increased by the employment of digitalis (see DRUGS); and this drug is useful even when no cardiac disease is present, although its good effects are still more marked when the congestion is dependent on disease of the heart. The constant drain of albumin from the body occasions anemia, which not only produces many unpleasant symptoms, but tends to cause fatty degeneration of various organs, from which there is no reason to believe that the kidneys are exempt. The administration of iron, therefore, is the chief remedy in structural disease of the kidneys and it is useful by diminishing or removing the symptoms of anemia and the tendency to fatty degeneration consequent thereon, and also by increasing the tone of the vessels, thus diminishing the loss of albumin.

T. LAUDER BRUNTON.

ALCOHOL. *SYNON.* *Ethyl-Alcohol*: *Vinæ Alcohol*, *Spirit of Wine* (C_2H_5O)—Alcohol is the product of a process of fermentation induced by the action of a microscopic fungus, *Yeast*, upon certain kinds of sugar, especially grape sugar, but also upon that derived from starch of any description, and, in the same manner, upon milk sugar. In this process a peculiar metamorphosis takes place, by which alcohol and carbonic acid are produced in considerable amount, together with very minute quantities of succinic acid, glycerine, and other bodies.

Alcohol may also be produced synthetically from its elements, carbon, hydrogen, and oxygen.

As alcohol is very volatile, boiling at 172° Fahr. (78° C.), it may readily be separated by distillation from the water with which it is at first combined. Other means must be resorted to, however, in order to separate the very ultimate particles of this water, as a strong attraction exists between the two liquids.

Alcohol, diluted with about 95 per cent. of water, and subjected to the action of another microscopic fungus, is oxidised into aldehyd and acetic acid.

PHYSIOLOGICAL EFFECTS.—Applied to the skin, alcohol produces a sensation of coolness, due to its rapid evaporation; but, if the application be continued sufficiently long, irritation

is excited. This latter effect ensues immediately if alcohol is brought into contact with a mucous membrane. Its strong attraction for water seems to be the chief cause of this action.

Alcohol is a powerful *antiseptic*, probably from the fact that it is capable, even when diluted, of preventing the development of septic germs, such as vibrios and bacteria, as well as of paralysing the activity of those already formed.

There is scarcely any other therapeutical agent the *internal action* of which varies so much according to the dose given. In *small quantity*, and slightly diluted with water, alcohol promotes the functional activity of the stomach, the heart, and the brain; whilst a like quantity, largely diluted, exerts but a limited influence upon these organs: if, however, the dose of alcohol be often repeated, it is readily assimilated; and, becoming diffused throughout the system, undergoes combustion within the tissues of the body, imparts warmth to them, and yields vital force for the performance of their various functions. Simultaneously with this consumption of alcohol, the body of the consumer is often observed to gain in fat—a circumstance due to simple accumulation, the fat furnished by the food remaining unburned in the tissues, because the more combustible alcohol furnishes the warmth required, leaving no necessity for the adipose hydrocarbon to be used for that purpose. A quantity of 100 cubic centimetres of alcohol *per diem* (about three and a-half fluid ounces)—equivalent to about one litre of Rhine wine of medium strength—is sufficient to supply between one-third and one-quarter the whole amount of warmth requisite for the human body during the twenty-four hours. The warmth so supplied cannot be measured by a thermometer, however, any more than can that furnished by the internal combustion of other hydrocarbons, such as the oils or sugars. The subjective impression of increased warmth usually experienced after taking a dose of any alcoholic liquid is deceptive, and is only due to an irritation of the nerves of the stomach, and to the increased circulation of blood through the cutaneous vessels, particularly those of the head.

Doses *somewhat larger*, but still sufficiently moderate not to cause intoxication, act, for the most part, in the same way, but, as an additional effect, they produce a distinct decrease of temperature in the blood, lasting half-an-hour or more. As far as the matter has hitherto been explained, this latter effect depends upon a directly depressing influence exerted by alcohol upon the working cells of the body, and upon a temporary paralysis of the vaso-motor nerves. The latter is followed, of course, by dilatation of the superficial vessels, particularly those of the head, in consequence of which a larger surface of blood is exposed, and the loss of heat by irradiation into the air is increased, the temperature of the circulating fluid being thus lowered; whilst, the combustion carried on by the cells being retarded, the generation of heat from this source is diminished. The quantity of carbonic acid eliminated is thus diminished, as is also the amount of urea excreted. After the organism has become inured to the action of alcohol, these effects upon the temperature of the blood are less distinctly, or not at all, marked.

The agreeable excitement at first caused by such doses of alcohol is succeeded by a reaction, characterised by lassitude and drowsiness, the latter condition usually lasting longer than the previous one of exhilaration.

The symptoms of intoxication produced by *large doses* of alcohol are sufficiently well known. When the abnormal condition of excitement in the brain induced by this stimulant has been kept up, almost without intermission, for a length of time; or when it is suddenly withdrawn after the organ has been long subjected to it; the disturbance brought about is so great and persistent as to result in a complete overthrow of the reasoning faculties, and the condition known as *delirium tremens* ensues. At the same time that this pernicious influence is being exerted upon the cells of the brain, fatty accumulations may take place in other organs, particularly in the liver, heart, and connective tissues; the blood-vessels become diseased; and, in many instances, cirrhosis of the liver, kidneys, and meninges makes its appearance, as part of the general disorder of nutrition. The shrinking of connective tissue, characteristic of this last-mentioned complication, seems to depend upon the direct irritation caused by the presence of an-oxidised alcohol.

Under ordinary circumstances, and after the consumption of moderate quantities of alcohol, only slight traces of it are to be detected in the urine, and none whatever in the breath. Pure alcohol imparts no taint to the exhalations of the body, the ethers and fuel oils, on the other hand, do so by reason of their being less readily combustible. It is very likely that alcohol is completely oxidised into carbonic acid and water during the process of assimilation; at least, no other secondary products resulting from its disintegration have as yet been detected.

THERAPEUTICAL APPLICATIONS.—There can be no doubt but that a healthy organism, supplied with sufficient food, is capable of performing all its regular functions without requiring any specially combustible material for the generation of heat and the development of vital force. But the case assumes a different aspect when, in sickness, it transpires that, while the metamorphosis of tissue goes on with its usual activity, or with increased energy, as happens in many diseases, the stomach, refusing to accept or digest ordinary food, fails to supply material to compensate for this waste. Here it is, then, that a material which can be most readily assimilated by the system, and which, by its superior combustibility, spares the sacrifice of animal tissue, is especially called for; and such a material we have in alcohol. Small but oft-repeated doses of alcohol, largely diluted with water, are generally well tolerated by the weakest stomach; and, thus given, the absorption and oxidation of the spirit goes on without difficulty or effort on the part of the patient's system.

According to the experiments of Dr. Frankland and others, the burning of 1.0 gramme of alcohol yields sufficient heat to raise the temperature of seven litres of water 1°C.; and the burning of 1.0 gramme of cod-liver oil suffices for nine litres. Now, in taking three table-

spoonfuls of the oil daily, we yield about the same amount of warmth to the body as is given by four table-spoonfuls of absolute alcohol—the quantity contained in a bottle of light claret or hock. The oil, however, is digested and oxidised by the organs of the body with difficulty, while, for the assimilation of the alcohol, scarcely any exertion of the working cells is required. Thus, it can be demonstrated by calculation, as above-mentioned, that heat-producing material, sufficient to supply nearly one-third the whole amount of warmth required by the body within twenty-four hours, is offered in a quantity of 100 grammes (about three and a-half fluid ounces) of alcohol. In this sense alcohol is a *food*; for we must regard as food not only the building material, but all substances which, by their combustion in its tissues, afford warmth to the animal organism, and, by so doing, contribute towards the production of vital force, and keep up the powers of endurance. Alcohol, therefore, diluted with at least 90 per cent. of water (in any convenient form of beverage), may be given with advantage, in small but oft-repeated doses, in most of the acute and chronic diseases where it is desired to sustain the strength of the patient, but where at the same time the digestive organs, from any cause, refuse to tolerate a more substantial form of nourishment, at least in quantities that would answer the necessities of the case. In such cases it is certainly not sufficient to call alcohol merely a *stimulant*. If alcohol served here only in the quality of a stimulant, its effect would soon pass away, leaving the patient more exhausted than ever; for the human organism is so constituted that it cannot be driven to perform its functions by the application of measures that simply stimulate, without supplying some new force to take the place of that put forth by the organs of the body under the impulse of excitement. To take a familiar illustration, alcohol thus given stimulates no more than does the easily burning coal which we put in small quantities upon a languid fire, to prevent its going entirely out.

Modium doses act powerfully upon the brain and heart, and are therefore serviceable as real stimulants in cases where it is desirable to excite the cerebral and circulatory systems to greater activity. We must not forget, however, that, while exciting this increased activity, such doses do not elevate the temperature of the body, on the contrary, where the effect can be measured, it is found that they depress it a little. By continuing to exhibit such doses, we can sometimes (in erysipelas, puerperal peritonitis, and similar diseases) lower febrile heat by alcohol where even quinine proves ineffectual. The consequences of this decline of fever-heat are an immediate restoration to consciousness, if delirium or stupor has been present; and, in any case, a general improvement in the feelings of the patient. Todd and his school, before the application of the thermometer, called this the effect of *stimulus*, while in reality the improvement is due almost entirely to the withdrawal or diminution of febrile disturbance. As fever patients can tolerate large quantities of alcohol without showing any sign of intoxication, it is allowable, and sometimes even neces-

sary, to rise in the scale of doses beyond the limits ordinarily prescribed.

Of late years alcohol has been given during the night to hectic phthisical patients as a preventive against copious and exhausting attacks of sweating, and with a gratifying amount of success. Such patients certainly tolerate the remedy much better than has hitherto been generally supposed. It need hardly be said that, in cases of cardiac excitement, not resulting from fever, alcohol is at least to be used with caution.

MODES OF ADMINISTRATION.—One of the most important, but at the same time most difficult, points for decision is the exact nature and quality of the alcoholic drink to be prescribed or allowed to a patient, who may require alcohol in some form. For general use, a pure Claret, Hock, or Mosel wine are the preparations most to be recommended. Cognac, Champagne, old Gin or Whisky, and the heavier Southern wines, may also be used according to circumstances. But whatever drink may be selected, it must at least be free from fusel oil to such an extent that a healthy man, even after imbibing a considerable quantity, will not feel any other effects than those of a pure stimulus; that is to say, an agreeable exhilaration of spirits, neither accompanied by a sense of weight in the head, nor followed by that persistent overfilling of the cerebral vessels and dulness of ideas characteristic of the physiological effects of fusel oil.

The *Fusel Oils* (so called from their oily qualities) consist chiefly of propyl, butyl, and amyl alcohol, of which the last-named forms the largest proportion. In order to examine any specimen of alcohol with reference to its purity from these objectionable constituents, it is only necessary to rub a few drops between the palms of the hands for half a minute, by which rapid evaporation is caused, and then to smell the moist spot left on either palm. If the alcohol be pure no odour whatever should remain, as ethyl alcohol evaporates very quickly, amyl alcohol, on the contrary, is much less volatile, and, if present in the liquid, will not have evaporated, so that its peculiar and unmistakable odour will remain to attest its presence as an impurity in the specimen examined.

This test is not applicable to the more complicated liqueurs and wines, as these all contain certain odiferous organic principles of their own that might disguise the smell of the fusel oil. The inoffensive quality of any given preparation, as a wine or spirit, can only be relied upon when one knows by experience that it is pure; and then it should always be obtained, if possible, from the same source, so as to ensure uniform purity.

By far the most pernicious of all the ordinary drinks in use is the spirit obtained from potatoes, as this contains the largest proportion of fusel oil. Even after being redistilled, this liquor is still tainted with the poison to a fearful extent. Of course, wines mixed with such spirit possess the same objectionable qualities; whilst wines made from must to which potato-sugar has been added are likewise tainted, though to a less degree. It can easily be demonstrated by experiments upon animals, that amyl alcohol is the agent to the presence of which the extremely poisonous

action of many drinks upon our nerves and other organs is due. All distilled drinks made from other sources than from grapes contain it to a greater or less extent.

To facilitate the process of estimating the quantity of any particular beverage necessary to be administered in order to produce a given effect, a table is subjoined showing the percentage of absolute alcohol contained in average specimens of the different kinds of wine, beer, &c., in common use.

absolute Alcohol contained in—

Kumiss (a fermented liquor made from whey) is from 1 to 3 vol. per cent.
German Beer¹ is from 3 to 5 vol. per cent.
Hock or Claret is from 8 to 11 vol. per cent.
Champagne is from 10 to 13 vol. per cent.
Southern Wines (Port, Sherry, Madeira, &c.) is from 14 to 17 vol. per cent.
Brandy and the stronger liquors is from 30 to 50 vol. per cent.

For *antipyretic* purposes one will need to give an adult daily not less than the equivalent of fifty cubic centimetres (about two fluid ounces) of absolute alcohol, in divided doses within an hour or two. Taking this as a starting-point, the dose suitable for each individual case can be estimated accordingly.

The great quantity of carbonic acid contained in certain 'sparkling' wines acts upon the temperature of a fever patient much in the same favourable manner as the alcohol itself, and when alcohol is to be taken as a food, it would seem that the impregnation with carbonic acid facilitates its absorption.

All that has been stated thus far with regard to the use of alcohol in sickness applies to children as well as to adults. Of course no reasonable person would accustom healthy children to the use of alcoholic beverages; but, in cases of disease, really good and pure wine or brandy can be advantageously employed, even for infants, either as a *stimulant*, an *antipyretic*, or as an *article of food*, according to circumstances.

For *external use*, alcohol has been superseded by various more modern agents, of which eucalyptic and salicylic acids may be mentioned as the most important. In this connection the author cannot omit to notice one method of applying alcohol, suggested by Dr Richardson, namely, the treatment of diphtheria affecting the throat, by means of the inhaler, which projects the alcohol-spray with considerable force upon the infected mucous membrane, causing it to penetrate more deeply than any other caustic would be likely to do.

C BINZ (Bonn).

ALCOHOLIC INSANITY. See ALCOHOLISM, and INSANITY.

ALCOHOLISM.—**DEFINITION.**—This term is applied to the diverse pathological processes and attendant symptoms caused by the excessive ingestion of alcoholic beverages. These are very different if a large quantity is consumed at once or at short intervals; or if smaller quantities are taken habitually; and hence they are

subdivided into those due to (a) *acute*, and (b) *chronic* alcoholism. To the *acute* forms of alcoholic poisoning belong the acute ecstacy of the alimentary mucous membrane, rapid coma, some cases of delirium tremens, and certain special forms of acute insanity; whilst to the *chronic* class are referred the prolonged congestions, the fatty and connective-tissue degenerations of the various organs and tissues, most cases of delirium tremens, nervous affections of slow onset and course, and the cachexia, which, in varying combinations, attend a continuously immoderate consumption of alcohol.

ÆTIOLOGY.—That ordinary vinic or ethyl alcohol, in any and every shape, is a sufficient exciting cause of such *chronic* affections is beyond a doubt; moreover, we find that the more concentrated the form in which it is taken, the more surely and rapidly are they induced, and that, although some beverages give a greater liability to certain forms of disease than to others, yet the ultimate tissue-changes produced by all are practically similar, and of a markedly degenerative character. The purest alcoholic fluids will also induce the *acute* forms; but some of the phenomena observed in the worst cases of alcoholic poisoning have been referred, with some probability, to admixture with fusel oil, essential oil of wormwood, cocculus indicus, and other substances, more deleterious even than ordinary alcohol itself. See ALCOHOL, and ANGINISM.

The *predisposing causes* of a sudden debauch, such as festive gatherings, example of companions, desire of relief from anxiety and melancholy, &c., scarcely require mention. Acute alcoholic coma is generally due to the rapid consumption of a large quantity, but occasionally it is caused by taking a smaller quantity in the presence of some special condition, such as starvation, prolonged exposure to cold, or debilitating disease.

Chronic habitual drinking is undoubtedly *hereditary* in many cases; not that the ancestors have necessarily been drunkards, but that the family is of unstable nervous organisation, and that the neurotic taint which shows itself in other members in such affections as epilepsy, hysteria, insanity, is manifested in these cases by an intense craving for alcohol. Sometimes a pernicious education, by fostering habits of indulgence in early youth, has led to subsequent excess; and the prescribing of stimulants has occasionally been productive of similar harm. In the experience of the writer, the exhibition of large doses in fevers and acute affections has never done this—indeed, in several instances, a great dislike to stimulants has been produced—but the custom of recommending small quantities to young people and women as a remedy in hysteria, hypochondriasis, neuralgia, and allied disorders, or to relieve the fatigues incident to their daily life, cannot be too strongly protested against. The effect of *occupation* is very marked. Brewers, publicans, portmen, and others who trade in alcohol are, as a class, very intemperate, and so frequently are commercial travellers (Thackrah). *Sedentary* employments, being more monotonous, are more baneful than out-door occupations. *Modest* and

¹ English beer will contain a little more, but the writer has made no personal examination as to exactly how much.

drink more freely than agricultural labourers; whilst night-labourers, cabmen, sailors when on shore, brewers' draymen, navvies, pitmen, and paddlers consume an enormous amount of alcoholic fluids. *Social influences*, such as domestic unhappiness, rate of wages, unhealthy dwellings, bad drinking water, or an intermittent supply, are important factors in the causation of drunkenness. Under some circumstances, alcoholic excesses do less injury than usual; for example, in persons whose employment leads to copious sweating, or necessitates abundant exercise in a keen air; and some constitutions resist their baneful influence to a remarkable extent.

PATHOLOGY.—A large amount of ardent spirits acts on the nerve-centres as a narcotic poison, and causes rapid death by coma. Smaller quantities produce intoxication, a companion with or followed by an acute congestion and catarrh of the alimentary canal, especially of the stomach and duodenum. Habitual dram-drinking, by altering the chemical composition of the blood, and checking the normal changes of its corpuscles, exerts an injurious influence on the nutrition of the tissues. This is increased by the lessened consumption of food, and by the alterations in the calibre of the blood-vessels, set up at first by a special action on their vaso-motor nerves, and afterwards maintained by degeneration of their coats, as well as frequently of the heart itself. Moreover, alcohol probably interferes directly with the nutrition of the cell-elements of the various organs as it circulates through them; and it retards the elimination of effete materials—carbonic acid, uric acid, and urea.

ANATOMICAL CHARACTERS.—(a) *Acute Alcoholism.*—Dr. Beaumont thus describes the appearances which he observed in the stomach of Alexis St. Martin, after an excess of alcoholic stimulants:—'lunar membrane morbid; considerable erythema, and some aphthous patches on the exposed surface, secretions vitiated.' On another occasion, 'Small drops of grumous blood exuded from the surface, the mucous covering was thicker than common, and the gastric juices were mixed with a large proportion of thick rosy mucus and mucopurulent matter slightly tinged with blood.' The *post-mortem* appearances in a case of rapid coma in a patient at King's College Hospital, after taking three pints of raw whiskey, were:—intense injection of the vessels of the pyloric end of the stomach and duodenum, with a peculiar blanching of the mucous membrane between them, giving rise to a vivid scarlet arborescent appearance on a white ground; two ounces of bloody serum in the pericardial sac, and about sixteen ounces in the right pleural cavity (the left being obliterated by old adhesions), double pneumonia of the lower lobes; extreme congestion of the kidneys; and engorgement of the large veins over the posterior part of the brain. Contrary to the usual statements, no alcoholic odour could be detected in the brain, and there was no increase of fluid in the ventricles. The heart, liver, and kidneys were fatty; but these changes were probably of older date. In similar cases Devergie has noticed a bright red colouring of the pulmonary tissue; whilst Tarssen found palmar erythema in two cases,

and meningeal hæmorrhages in five others. Death from *acute delirium tremens* leaves no marked characters; meningitis and coarse brain-lesions are extremely rare, whilst pneumonia is much more common. After repeated attacks, as well as in old drunkards, fatty degeneration of the viscera, and various other chronic changes are found.

(b) *Chronic Alcoholism.*—The amount of fat in the blood is increased, or it becomes more visible. Chronic congestion and catarrh of the stomach, leading to atrophy of the gland-cells, and an increase in the submucous connective-tissue, is very constant, but chronic ulcer is not frequent. The liver is at first enlarged from congestion, and may continue so from a subsequent infiltration with fat, but more frequently it shrinks owing to cirrhosis. Lobar emphysema, chronic bronchitis, and hypostatic pneumonia are common. The heart is flabby, dilated, and presents fatty infiltration or even degeneration of its muscular tissue; but it may be hypertrophied, probably as a result of constant disease of the kidneys. The arteries and endocardium are studded with atheromatous deposits, the capillaries are congested, and the veins varicose. The kidneys exhibit the fatty, or, more commonly, the granular form of Bright's disease. The muscles are pale and flabby, and even in the bones formation of fat takes place at the expense of the bony texture. The nervous centres are atrophied and tough, the convolutions are shrunken, the nerve-cells and nerve-fibres are wasted, and an increased amount of serous fluid exists in the ventricles and subarachnoid space. The abnormal adhesion of the dura mater to the cranium, the large Pachionian bodies, the opaque arachnoid, and the thickened pia mater, all testify to an exaggerated development of fibrous tissue. Occasionally hæmorrhage into, or softening of, the brain, consequent on the diseased state of its blood-vessels, is met with. The increase of connective-tissue is especially marked in *spirit-drinkers*, and explains the emaciated appearance, prematurely aged look, sunken cheeks, and wrinkled countenance which they generally present. The *beer-* and *wine-drinkers*, on the contrary are loaded with fat not only in the viscera, but in the subcutaneous tissue and the omenta, and hence these subjects are corpulent, with oily skins and prominent abdomens, even when the face and extremities are wasted. Gouty deposits are also frequent. These differences, however, are not nearly so absolute as is maintained by many writers. The presence of a variable amount of dropsy, a congested pharynx, chronically-inflamed conjunctivæ, turgid capillaries, and occasionally papules of acne rosacea on the face, complete the morbid anatomy of the confirmed toper. The autopsy in *alcoholic insanity* discloses no specific characters.

SYMPTOMS.—1. *Acute Intoxication.*—In this state the successive and varying mental phenomena, the disorders of common and special sense, and of the motor apparatus, are well known. These are followed by uneasy sensations and tenderness in the epigastrium, vomiting or retching, headache and vertigo, with dimness and occasionally yellowness of vision on stooping.

and rising again. The tongue is furred, the appetite is lost, and there is a constant feeling of thirst. The urine is copious and pale, but afterwards becomes scanty and loaded with urates. The countenance is sallow, and the general lassitude and depression are very marked.

2. *Acute Alcoholic Coma*.—In slight cases of this condition prolonged drowsiness is the chief symptom: but in the more severe forms the patient is quite insensible, the power of motion is in complete abeyance, the breathing is stertorous; the face is usually pale, the features remaining symmetrical, the pupils are generally dilated, though they may be contracted or even unequal, the pulse is slow and laboured; the skin feels cold and clammy, and the temperature is low—in one case it fell to 92° Fahr. There may be albuminuria; and occasionally the urine and feces are passed involuntarily.

3. *Chronic Alcoholism*.—The earliest symptoms of this form are muscular tremors, especially on waking; disturbed sleep, noises in the ears, dull headache, occasional vertigo, and disorders of vision. If there be also a foul breath, slightly jaundiced conjunctiva, watery eyes, and flabby features, with or without papules of acne rosacea around the nose and mouth, the combination is very characteristic. Irritable dyspeptic symptoms—the *romulus mutatus* of Huicland—and the signs of commencing or actual cirrhosis, or Bright's disease, or of fatty heart, frequently co-exist. As the affection advances, the incontinence and tremors increase, the mental condition becomes impaired, a striking deficiency of will and uncertainty of purpose are noticeable, the gait becomes ataxic, and the patient has a constant feeling of dread and anxiety.

4. *Delirium Tremens*.—This form of alcoholism occasionally supervenes on a single debauch, but it much more frequently affects the chronic drinker. It generally comes on during a drinking-bout, but this may have terminated before the attack commences. In some cases it is undoubtedly determined by prolonged abstinence from food, mental distress, surgical injury, or the onset of an acute disease, along with the ingestion of alcohol, but in others no cause but the habit can be traced. The first stage is indicated by inability to take food, marked anxiety and restlessness; tremor of the voluntary muscles, furred and tremulous tongue, cool skin, which is frequently bathed in perspiration; cold hands and feet, and a soft weak pulse. There is complete insomnia, or short periods of sleep are interrupted by terrifying dreams, and the patient's nights are tormented with visions of horrid insects, reptiles, and other objects pursuing him and eluding his attempts to escape from them or to seize them. Illusions of hearing are not uncommonly added; but the sense of smell is much more rarely involved. If there is no improvement, these not only haunt his nights, but persist in the day-time; he becomes more incoherent, his mental alienation increases, and attempts at suicide are common. The pupils are now minutely contracted, but there is no intolerance of light. The pulse quickens, and is very feeble or even dicrotic; and the general symptoms become more marked.

A prolonged sleep may occur in this stage, and the disease thus terminate. If it continues, the strength fails: the pulse becomes small, weak, and thready; the tremor increases; the tongue gets dry and brown in the centre; persistent coma-vigil and subultus tendinum come on; the patient talks incessantly, and picks at the bed-clothes; and death is ushered in by a delirious calm, or takes place in a paroxysm of violence. The writer has known cases in which the attack of delirium tremens always began by several severe epileptic fits.

5. *Alcoholic Insanity*.—The forms of insanity caused by alcoholism are *acute mania* and *melancholia*, *chronic delirium*, and *oimomania*. In the first homicidal impulses, and in the second strong suicidal tendencies, due to actual delusions and not to mere passive terrors, are added to the other signs of delirium tremens. Oimomania is a peculiar form of insanity, in which the patient breaks out into paroxysms of alcoholic excess, attended with violent, strange, or even indecent acts, due to apparently uncontrollable impulses. The attack lasts a few days, and is succeeded by a long interval of sobriety and chastity. These patients have generally some hereditary taint; and not unfrequently evidences, though often slight, of a morbid mental state may be detected in the intervals, if very carefully looked for. See INSANITY.

Complications.—Most of these have been pointed out, but chronic drinkers are especially liable to pneumonia of a low type, and to rapid phthisis. Delirium tremens is very rarely complicated with meningitis; acute alcoholic gastric catarrh may be followed by jaundice; and cerebral hemorrhage may come on in a drunken fit. Temporary albuminuria is occasionally caused by the ingestion of large quantities of spirits, and even of beer.

Diagnosis.—The diagnosis of acute alcoholic gastric catarrh, of insanity from alcohol, and of oimomania depends on obtaining a true history. Acute alcoholic coma can only be diagnosed with certainty by emptying the stomach and examining its contents. More odour of the breath is quite fallacious; and the writer attaches but little importance to the state of the pupils, or to the general features of the coma. Convulsions sometimes usher in the condition; and apoplexy may arise from the accidental rupture of a blood-vessel whilst a person is drunk. Opium-poisoning can only be satisfactorily eliminated by examining the contents of the stomach. Uremic poisoning may be diagnosed by testing the urine, though here an element of uncertainty is introduced by the occasional occurrence of albuminuria in alcoholic cases; the presence of hypertrophy of the heart, of dropsy, of casts in the urine, or other changes typical of Bright's disease, must decide the question. Delirium tremens is occasionally separated with difficulty from some forms of insanity not caused by drink; but in these cases delusions, not mere terrors or hallucinations, are of primary importance. The delirium of acute fever, and pneumonia may be mistaken for delirium tremens; but the pyrexia, history of the case, and physical condition of the patient will guide to a correct diagnosis if the possibility of error

is remembered. Chronic alcoholism has been mistaken for other chronic nervous affections, such as locomotor ataxy, chronic softening and multiple sclerosis of the nerve-centres, paralysis agitans, chronic tremors from metallic poisons, senile dementia, and commencing general paralysis. In all these maladies, special symptoms are present, besides those common to them and to chronic alcoholism.

Prognosis.—In the acute forms of alcoholism the prognosis is favourable so far as the immediate attack is in question. In acute coma, the patient generally, but by no means invariably, rallies from the state of insensibility; but he may die from the superposition of a very rapid pneumonia. The prognosis in delirium tremens is favourable in young subjects; but its gravity increases with every attack, and with the co-existence of disease of the viscera, especially of the heart, liver, or kidneys. Patients with marked symptoms of fatty heart, or in whom pneumonia sets in, but rarely recover. Chronic alcoholism may be temporarily arrested; but the ultimate issue is unfortunately as a rule only too certain, for the habit is in most cases too strong to be broken off, or even to be checked for any lengthened period. Mental impairment, persistent tremors, ataxy, and signs of coarse brain-lesions, are especially significant of a speedy termination.

Treatment.—The acute gastric catarrh is most rapidly subdued by washing out the stomach with copious draughts of tepid water, and then giving a saline purge. All forms of alcohol should be rigidly abstained from; and the diet must be simple, and taken in a fluid form for a day or two. Passive exercise in the open air, or, if the patient be vigorous, a brisk ride on horseback, is very beneficial.

In cases of acute coma the stomach should be at once emptied by means of the stomach-pump. Cold affusion, followed by energetic friction and the application of bottles filled with warm water, so as to keep up the temperature, will generally revive the patient. Galvanism, in the form of the interrupted current, may often be employed with advantage. If the patient be strong, a smart purge, or, if weak, a milder one, will be all the after-treatment that is necessary.

Delirium tremens must be treated differently in the young and in the old. In first attacks in young subjects, complete abstinence from alcohol, light and easily assimilated food (milk diet), moderate purgation, and occasionally antimony in doses of one-eighth of a grain, carefully watched, have been most efficacious in the writer's hands. If the patient has two or three restless nights in succession, bromide of potassium (thirty grains), or chloral hydrate (twenty grains), may be given at intervals of four hours, until sleep is procured; but as the disease is spontaneously curable, sedatives must not be pushed. An experienced attendant should be always present, but no form of mechanical restraint is permissible. In older cases, a mild purge should begin the treatment; and light but very nourishing food should be administered at short intervals. Milk, hard-boiled, raw eggs beaten up with milk, strong soups, and such articles are to be given freely; and, by careful management and good nursing,

a very severe attack may be tided over, and natural sleep will return in from three to five days. The early administration of sedatives is to be deprecated, but should the restlessness persist, in spite of careful and assiduous feeding, a full dose of laudanum (m xxx.—xl.) at bed-time is of great value. In the absence of albuminuria, lung-complications, or any sign of failure of the heart's action, the writer prefers this drug to other sedatives. If the opium alone fail, its combination with an alcoholic stimulant (brandy, whisky, or stout) often succeeds. If there be any tendency to syncope, or if pneumonia should come on, as well as in cases complicated with shock, as in surgical injuries, a free use of stimulants is imperative. Hypodermic injections of morphia, and large doses of digitalis, are recommended by many authorities; but the writer has seen great harm attend their free exhibition. The cautious inhalation of chloroform vapour has occasionally cut short an attack by inducing sleep, but it much more frequently fails. Mechanical restraint is seldom, if ever, necessary, if the patient be properly nursed and attended to. All methods of self-destruction must be carefully guarded against; and a padded room, when available, is of the utmost benefit.

The great desideratum in chronic alcoholism is to substitute an easily-digested and nourishing diet for the alcoholic stimulants, which can then be safely dispensed with altogether. The practitioner's judgment, and his knowledge of the cuisine, are very important in the management of these cases. Strong meat-soups and good specimens of the concentrated preparations of meat are of great value. The strictly medicinal treatment will consist in the administration of bitter tonics, such as nux vomica, quinine in small doses, calumba, or gentian; with emminatives, such as spirit of chloroform, armoreia, and capsicum. Alkalies, effervescent mixtures, and hydrocyanic acid are peculiarly useful if the stomach is irritable. The condition of the liver and bowels should be carefully regulated. Bromide of potassium is in general the best sedative to employ against the insomnia, though chloral hydrate is more certain; but the latter should only be given occasionally, lest the patient fall into the habit of frequently resorting to it. In long-standing cases, cod-liver oil, arsenic in small doses, and oxide of zinc have all done good, but they require a long and protracted administration. Phosphorus has been of no use whatever in the cases in which the writer has tried it; but small doses of the more easily assimilable preparations of iron are occasionally well borne, and are then most useful. The craving for drink, if urgent, may be checked by small doses of opium, but this drug must be exhibited with extreme caution. Judicious supervision, and, in inveterate cases, a residence in a proper asylum, are the only means from which any permanent benefit can be expected. The treatment of insanity induced by alcoholism will not differ from that recommended in other forms, except in an enforced abstinence from its cause.

JOHN CURNOW.

ALGID (*algids*, cold).—A word implying extreme coldness of the body, used only when it arises in connection with an internal morbid state, such as cholera, or a special form of malignant remittent fever.

ALGIERS.—Warm winter climate. Mean winter temperature 59° F., liable to rapid changes. Heavy rains not infrequent. See CLIMATE.

ALIMENT.—Food or aliment furnishes the elements required for the growth and maintenance of the organism; and, through its action with the other life factor—air, forms the source of the power manifested.

The aliment of organisms belonging to the vegetable class is derived from the inorganic kingdom. Under the influence of the sun's rays the inorganic principles are applied to growth, and constructed into organic compounds. This constitutes the main operation of vegetable life, and in it we have the source of the aliment of animals, which can only appropriate organic compounds, and which either directly or indirectly derive these compounds from the vegetable kingdom. As the solar force employed in the construction of organic compounds, through the agency of the vegetable organism, becomes locked up in the compound formed, such compound represents matter combined with a definite amount of latent force. In the employment, therefore, of organic matter as aliment by animals, we have to look upon it not only as yielding the material required for the construction and maintenance of the body, but as containing and supplying the force which is evolved under various forms by the operations of animal life.

Aliment constituting the source from which the several elements belonging to the body are derived, it follows that to satisfy the requirements of life it must contain all the elements that are encountered. It is not, however, with the elements in a separate state that we have to deal, but with the products of nature in which they are variously combined.

The *alimentary products* as supplied by nature are resolvable by analysis into a variety of definite chemical compounds. These constitute the *alimentary principles*. Some are common to both animal and vegetable food, as for instance albumen, caseine, fat, &c.; others are peculiar to either the animal or vegetable kingdom. Starch, for example, is met with only in vegetable, and gelatine only in animal products.

With reference to the alimentary principles, it must be understood that in no case do they exist in natural products in an isolated form, and no single alimentary principle is capable of supporting life. Although, however, it is with the alimentary products as a whole that we are practically concerned, yet, regarded from a scientific point of view, a knowledge of these constituent principles is required, to enable us to assign to them their proper value as alimentary articles; and for the purpose of systematic consideration some kind of classification is needed.

CLASSIFICATION.—Prout classified the constituent principles of food into four groups, which he named (1) the *aqueous*; (2) the *saccharine*; (3) the *oleaginous*; and (4) the *albuminous*. This classification is defective, inasmuch as it

omits from consideration saline matter which is equally as essential to nutrition as any other part of an alimentary product. The saccharine and oleaginous groups also stand as primary and independent divisions, whilst physiologically they are related, and may be conveniently considered under a combined heading.

Liebig proposed a classification based on physiological principles; and, taking into account only the organic constituents of food, grouped them under the heads of (1) *plastic elements of nutrition*; and (2) *elements of respiration*. His *plastic elements of nutrition* comprise the nitrogenous principles; and to these he assigned the office of administering not only to the growth and renovation of the tissues, but also to the production of muscular and nervous power. Believing that the source of these powers issued from the oxidation of the respective tissues, he held that the exercise of muscular and nervous action created a corresponding demand for nitrogenous alimentary matter, which thus became invested with an importance that led it to be regarded as affording a measure of the value of an alimentary article. By recent experimental research this view has been found to be untenable. The nervo-muscular organs are now looked upon as holding the position of instruments, by whose agency the force liberated by chemical action is made to manifest itself under certain other forms; and what is wanted for the purpose is simply oxidisable organic material, which may be derived from non-nitrogenous as well as nitrogenous food. The *elements of respiration* or, as they were afterwards more appropriately styled, the *calorific principles*, represent the organic non-nitrogenous constituents of food. Their destination, according to Liebig, was heat-production. It is now maintained, however, as stated above, that they play a part in connection with nervo-muscular action; and it may be also said that they are to some extent concerned in tissue-development. From the considerations set forth, Liebig's classification loses the scientific value it was at one time supposed to possess.

The following grouping of the alimentary principles based on chemistry furnishes a classification which involves no theoretical proposition, and is practically convenient:—

Food is primarily divisible into *Inorganic* and *Organic* principles.

The *Inorganic* principles consist of water, and the various saline matters required by the system. They are as much needed for the support of life as the organic portion of food.

The *Organic* principles are sub-divisible into *Nitrogenous* and *Non-nitrogenous*; and the *Non-nitrogenous* are again further sub-divisible into *Hydro-carbons* and *Carbo-hydrates*.

The *Nitrogenous* principles contribute to the growth and nutrition of the various bodily textures, and furnish the active agents of the secretions. They also undergo resolution in the system into urea, which is excreted; and a complementary hydro-carbonaceous portion, which is susceptible of application to force-production. They are thus capable of administering to all the purposes fulfilled by the organic portion of an aliment.

The *Hydro-carbons* or *Fats* are applied to the

production of heat and other forms of force. They seem also to be essential to tissue-development generally, besides yielding the basis of the adipose tissue.

The *Carbo-hydrates* (starch, sugar, gum, &c.) contribute to the formation of fat, and are also applied indirectly if not directly to force-production.

There are a few principles, such as alcohol, the vegetable acids, and pectin or vegetable jelly, which do not strictly fall within either of the preceding groups. Alcohol occupies a chemical position intermediate between the fats and carbo-hydrates; whilst the others mentioned are more highly oxidised compounds than the carbo-hydrates.

All alimentary products in the form supplied by nature contain organic and inorganic principles, and the organic principles comprise more or less of the nitrogenous and non-nitrogenous kinds; but the non-nitrogenous do not necessarily, and indeed do not generally, include both hydro-carbons and carbo-hydrates. In milk, however, which may be regarded, from the position it holds in nature, as furnishing a typical representation of an alimentary article, principles exist belonging to each of the groups enumerated in the above classification. See Diet.

F. W. Pavy.

ALIMENTARY CANAL. Diseases of. See DIGESTIVE ORGANS, Diseases of, and the several organs.

ALKALINITY.—The reaction of human blood is always alkaline; and, though the normal degree of alkaliescence has not yet been determined, it is probable that, like the temperature of the body, it is tolerably constant. In disease considerable variation, no doubt, occurs, but still the blood is always found alkaline. Pettenkofer and Voit found the serum of blood acid in a case of leukaemia some few hours after death, but not during life; and Dr. Garrod states that in chronic gout the serum may become somewhat neutralized, but never acid. F. Hoffman has also found that the blood retains its alkalinity with great obstinacy; he fed pigeons for a considerable length of time on food yielding only acid ash, but the animals suffered from blood-poisoning before the alkalinity of the serum was neutralized. The alkalinity of the blood is maintained by the constant passage into it of the alkaline salts of the food, and of alkaline carbonates derived from the oxidation of the lactic, oxalic, and uric acids furnished by the disintegration of the tissues. The blood is probably prevented from becoming too alkaline by the withdrawal of its alkaline salts by the alkaline secretions, namely, the saliva, the bile, and the pancreatic fluid; whilst the acid salts, which, if accumulated, would tend to depress its normal alkalinity, are removed by the acid secretions, namely, the sweat, the gastric juice, and the urine, and by the exhalation of carbonic acid from the lungs. It has been shown that the withdrawal of acid by one secretion has a decided effect on the reaction of other secretions; thus the saliva becomes more alkaline during digestion, when the stomach is pouring out the acid gastric juice; and Dr. Bence Jones has shown that

during digestion the acidity of the urine is lessened. A similar relationship is also shown to exist between the elimination of carbonic acid by the lungs and the acidity of the urine, the latter falling as the former is increased, and *vice versa*. The importance of a proper degree of alkaliescence for the blood is obvious, when we consider that this condition increases the absorption-power of its serum for gases, and is necessary to maintain its albumin in the liquid state, whilst oxidation is always more perfectly performed in alkaline solutions.

ALKALIS.—**DEFINITION.**—Inorganic substances, which turn syrup of violets green, and turmeric brown; and restore the blue colour to litmus which has been reddened by acids. They combine with acids to form salts, and their carbonates are soluble in water.

ENUMERATION.—The only substances which correspond with the above definition are—Potash, Soda, Lithia, and Ammonia. The alkaline earths—Lime, Magnesia, Baryta, and Strontia, and the organic alkalis, have a similar action on vegetable blues and yellows; but the carbonates of the former group are almost insoluble in water, whilst the latter contain carbon, and are therefore classed with organic substances.

PROPERTIES.—Ammonia is distinguished from the other alkalis by its volatility. The non-volatile alkalis are readily recognised by their spectra, and by the colour they impart to the blowpipe flame, potash giving it a violet, soda a yellow, and lithia a carmine colour. Potash and soda are present as constituents of the body in considerable quantities, ammonia exists to a smaller amount, and lithia probably in traces. Soda is found chiefly in the blood, potash in the muscles.

ACTION.—When applied to the skin dilute alkalis and their carbonates act as rubefacients. Pure ammonia is a vesicant, and potash and soda have a caustic action. Both caustic potash and soda absorb water from the tissues, and form a corrosive fluid, which destroys the parts around, as well as that to which the caustic has actually been applied. To prevent this effect they are sometimes mixed with lime, which absorbs the water. A mixture of potash and lime forms the Vienna Paste. When inhaled, ammonia causes irritation of the respiratory passages, and increased secretion of mucus. This irritation excites reflex contraction of the blood-vessels and consequent rise of blood-pressure. When swallowed in quantity, the caustic alkalis and their carbonates produce symptoms of irritant poisoning. In the case of ammonia these symptoms may be accompanied by those of inflammation of the air-passages, caused by the irritant vapour. The best antidote is dilute acid, such as vinegar. In small quantities and diluted, alkalis increase the secretion of gastric juice. After absorption into the blood they render this fluid more alkaline; whilst potash appears especially to accelerate tissue-change, and is accordingly classed among the alteratives. When injected directly into the blood, potash acts specially on the muscles, which it paralyzes. Ammonia stimulates the motor centres in the brain and spinal cord, the

respiratory centre in the medulla oblongata, and the accelerating nerves of the heart. When injected into the veins it therefore causes convulsions like those of strychnia, and quickening of the respiration and pulse. Alkalies are chiefly excreted by the urine; and potash, soda, and lithia lessen its acidity, or render it alkaline. Ammonia is partly excreted unchanged, but a portion passes out in the form of uric acid; and it does not render the urine alkaline like the others. Potash and lithia act as diuretics, soda to a less extent; and ammonia least of all. The diuretic action does not depend on any change in the blood-pressure. Potash and ammonia are diaphoretic. Potash lessens the tenacity of mucus.

Uses.—Dilute solutions of potash and soda relieve itching in skin diseases. Caustic potash or soda is used to destroy warts; to cauterize poisoned wounds and ulcers; to open hydatid cysts in the liver; and to establish issues. Ammonia neutralizes the formic acid which renders venomous the stings of bees, ants, and mosquitoes, and is therefore applied to relieve the pain which they cause. The intravenous injection of ammonia has been recommended as an antidote in snake-poisoning; but the value of the remedy is not established. Mixed with oil, so as to form a liniment, ammonia is used as a rubefacient in sore throats, bronchitis, rheumatic pains, and neuralgia. It is inhaled to relieve headache; as a restorative in syncope and shock, when it raises the blood-pressure, and to facilitate expectoration in chronic bronchitis. Alkalies administered after meals act as antacids, and relieve heartburn. When given before meals they increase the secretion of gastric juice, quicken digestion, and relieve weight at the epigastrium, pain between the shoulders, and flatulence. Bicarbonate of soda is usually given for this purpose, but when the stomach is very irritable liquor potassæ is preferred, as it is considered to have a sedative action on the mucous membrane. Alkalies appear to lessen the transformation of glycogen into sugar, and they are used on this account in diabetes. Liquor potassæ sometimes helps to reduce obesity. Alkalies are used in the treatment of scrofula, rheumatism, gout, and lithiasis; but in the two last-mentioned lithia is considered the most valuable, whilst potash is preferred to soda, as the urate of lithia is most soluble, and the urate of soda least so. The salts of certain organic acids, such as the acetate or citrate, may be employed as remote antacids to render the urine alkaline, as they undergo combustion and are converted into carbonates in the blood. Alkalies are given to lessen the acidity of the urine in inflammation of the bladder or urethra, and potash is employed as a diuretic in dropsies. On account of its stimulating action on the heart and respiration, ammonia is administered in adynamic conditions and in chronic bronchitis.

T. LAUDER BRUNTON.

ALKALOIDS and other ACTIVE PRINCIPLES.—DEFINITION.—An alkaloid is a substance formed in the tissues of a plant or of an animal, having a definite composition as regards the proportions of the chemical elements of which it is composed, and capable of combining, like an alkali, with acids to form salts.

Besides alkaloids there are other active principles found in plants, which have also a powerful influence on the animal economy but do not possess all the chemical properties just stated.

CHEMICAL COMPOSITION AND RELATIONS.—These are briefly expressed in the above definition. Thus morphia, one of the alkaloids of opium, has always the chemical composition represented by the formula $C_{17}H_{19}NO_3$, and it may unite with acetic acid to form acetate of morphia, just as potash may unite with the same acid to produce acetate of potash. But the empirical formula $C_{17}H_{19}NO_3$ represents only the percentage composition of the substance in the simplest numbers, and does not express how the atoms of the different elements are related to each other. For, just as ethylic alcohol, with the composition C_2H_5O , is believed by the chemist, from its behaviour towards other bodies, to contain a 'radicle,' or group of atoms, C_2H_5 , having certain chemical properties resembling those of a base, such as potassium, K; and just as this radicle, C_2H_5 , may replace one of the elements of water, so as to form alcohol ($C_2H_5 + H^2O = \frac{C_2H_5}{H} O + H$); so chemists have

good reason for believing that alkaloids belong to the group known as *amines* or *amides*, which are really ammonia, NH_3 , in which one or more of the atoms of hydrogen are replaced by a radicle or radicles. It is impossible, however, in the present state of knowledge, to represent the true chemical composition of alkaloids, the exact constitution of the radicles being still unknown.

It is obvious that two or more alkaloids may resemble each other in percentage composition, and still be very different, both in their chemical structure and, necessarily, in their physiological action. Thus strychnia, $C_{21}H_{27}N_3O_2$, quinia, $C_{20}H_{21}N_3O_2$, and cinchonina, $C_{20}H_{21}N_3O_2$, differ only in a few atoms of carbon or of oxygen, more or less; but they have different physiological actions, showing that their chemical structure, which is not indicated in these formulæ, must also be different. The physiological action of an alkaloid may also be modified by combining it with another substance. Thus, as was pointed out by Crum-Brown and Fraser, compounds of strychnia with methyl, ethyl, and amyl, do not present the well-known physiological action of that substance, but one analogous to that of woorin.

ENUMERATION.—The alkaloids and other active principles most familiar to the physician are:—Morphia, Apomorphia, Narceia, Codeia, Thebais, Narceotin, Papaverin; Atropia, Hyoscyamia, Daturia; Nicotin; Conia; Phystigmina; Strychnia, Brucia; Quinia, Cinchonina, Berberia, Caffin; Accenia, Veratria; Digitalin; Cararia; Muscaria; Santonia; and Ergotin.

SOURCES.—The majority of alkaloids are formed by plants. The function which they subserve in the economy of the plant is not known. Some plants produce only one alkaloid, while in others two or more may be found. A few of the alkaloids have been produced synthetically by the chemist.

PHYSIOLOGICAL ACTION.—Alkaloids have various degrees of physiological activity when

introduced into the animal body. Many are slow in their action, and a large dose is required to produce any observable effect; while others act more rapidly, and are so potent that even a minute dose may destroy life. Compare, for example, narcotin, one of the alkaloids of opium, with nicotine, the alkaloid of tobacco. Twenty to thirty grains of the former have been taken by the human subject without producing any marked symptoms, while the twentieth part of a grain of the latter may induce symptoms so severe as to threaten death. It is also well known that alkaloids may have a different kind of action on different animals. Thus one-fourth of a grain of atropia will produce serious symptoms of a complex character in a dog, while three or even four grains may be given to a rabbit without causing any more marked effect than dilatation of the pupil. In considering the physiological actions of these substances the following generalizations may, in the present state of science, be made tentatively:—1. As a general rule, the more complex the organic molecule, and the greater the sum of the atomic weight, the more intense will be the action of the substance. This has been shown in experiments on the action of the chinoline and pyridine series of bases by McKendrick and Dewar. 2. Substances which split up quickly into simpler bodies, produce rapid but transient physiological effects, whereas substances which resist decomposition in the blood or tissues may produce no appreciable results for a time, but when they do begin to break up, the effects are sudden and violent, and usually last for a considerable time. 3. Alkaloids have frequently a double action on different parts of a great physiological system, and their action in a particular group of animals will depend on the relative degree of development of the parts of the system in that group. Thus most of the alkaloids of opium have such a double action—a convulsive action resembling that of strychnia, due to their influence on the spinal cord or on the motor centres in the brain; and a narcotic or soporific action resembling that of anaesthetics, due to their influence on sensory centres in the brain. Hence, in animals where the spinal system predominates, as in frogs, these alkaloids act as convulsants; while in the higher mammals their principal action is apparently on the encephalic centres, which have now become largely developed.

Passing to the consideration of the action of the individual substances, we cannot do more than give, by way of example, a brief résumé of our knowledge regarding a few of them.

1. *Morphia*, $C_{17}H_{19}NO_3$ —an alkaloid of opium. In the frog this substance has an action resembling that of strychnia. At first there is a state of agitation, followed by tetanic spasms; finally, all reflex actions, including those of the heart and of respiration, are paralysed. Pigeons have been found to possess a remarkable power of withstanding the influence of this drug—an ordinary-sized bird requiring about two grains to kill it. Rabbits become partially somnolent, show a tendency to reflex spasms, and tolerate a large dose—say about one-half to one grain per pound weight of the animal. In the dog the subcutaneous injection of even one-tenth of a

grain (for a small animal) causes agitation followed by sleep; the pulse and respiratory movements are slowed; the smaller arteries become (at least during one stage) contracted, so as to cause an augmentation of general blood-pressure, the pupil is contracted; and, if the dose be large, death may be preceded by convulsions. In the higher mammals morphia acts chiefly on the sensory apparatus, both peripheral and central.

2. Other alkaloids of opium have also been investigated.—(a.) *Narceia*, $C_{22}H_{23}NO_3$, is a pure hypnotic, causing profound sleep. Even in large doses it does not produce convulsions. (b.) *Codéia*, $C_{17}H_{21}NO_3$, has an action like that of morphia. (c.) *Thebain*, $C_{19}H_{21}NO_3$, causes tetanic convulsions, thus resembling strychnia. (d.) *Narcotin*, $C_{22}H_{23}NO_7$, is slightly narcotic, but strongly convulsant. (e.) *Papaverin*, $C_{20}H_{21}NO_4$, causes a somniferous action like that of narceia. *Apomorphia*, $C_{17}H_{17}NO_3$, a derivative of morphia, has none of the characteristic actions of that substance, but acts chiefly as a vascular depressant and as an emetic. It is evident, therefore, that opium, which may contain more or less of all of these substances, must have an action on the body of a very complicated character.

3. *Strychnia*, $C_{21}H_{22}N_2O_8$ —the alkaloid of *Strychnos nux vomica*. In the frog very minute doses cause convulsions of all the voluntary muscles, excited by peripheral irritation. These convulsions are due to the action of the poison on the spinal cord, as they persist after decapitation. In warm-blooded animals the reflex character of the convulsions is less evident; they have more of a tonic character, and chiefly affect the extensors. The exact *modus operandi* of the poison on the cord is unknown, but in some way or other it heightens its reflex sensibility. Death is usually the result of asphyxia from arrest in spasm of the respiratory mechanism, but it may result from exhaustion. *Brucia*, $C_{22}H_{22}N_2O_8$, another substance found in *nux vomica*, appears to have an action like that of strychnia, but more feeble.

4. *Atropia*, $C_{17}H_{23}NO_3$ —the alkaloid of *Atropa belladonna*. In the frog it causes tetanic reflex spasms. Herbivorous animals, as a rule, have a tolerance of this poison, so that its effects are best studied in carnivora. Even in these the action is somewhat uncertain. Respiration may be paralysed without general convulsions: the pulse is quickened by paralysis of the inhibitory action of the pneumogastric nerve on the heart; and the arterial pressure is increased. After very large doses the arterial pressure may be diminished with paralysis of all parts containing involuntary muscular fibre. Secretion is diminished. The pupil is dilated apparently by a direct influence of the poison on the centres or nervous arrangements in the iris itself, as the effect may be observed even in an eye removed from the head. *Hyocyamia*, the alkaloid of *Hyoscyamus niger*, and *Daturia*, the alkaloid of *Datura stramonium*, have an action like that of atropia.

5. *Digitalin*, $C_{47}H_{87}O_{15}$ —the active principle of *Digitalis purpurea*. A large dose causes slowing of the heart's action, and if the dose be increased the heart will be arrested in diastole

and will not respond to direct excitation. With medium doses there is a period of acceleration of the heart's action, but this period may rapidly pass into that of slowness just mentioned. This action on the heart has not yet been clearly accounted for, and it remains to be decided whether it be due to the influence of the drug on the terminations of the pneumogastric, or of the sympathetic, or on the intracardiac ganglia themselves. Coincident with the action on the heart, the smaller arteries are contracted and the arterial tension is increased. Digitalis would appear to have little effect on involuntary muscle, but it exerts a potent action on voluntary muscle, which, after small doses, becomes feeble in contractile power, while large doses may abolish contractility altogether.

6. *Physostigma*, $C_{15}H_{21}N_2O_2$, — the active substance of *Physostigma venenosum*, or Calabar bean. As has been pointed out by Professor Fraser, this alkaloid has an action antagonistic to that of atropia. Sensibility and consciousness remain until death; the voluntary muscles are paralysed; involuntary muscles are said to show tetanic contractions; respiration is at first accelerated, and afterwards slowed, the vessels become alternately dilated and contracted; secretion, especially that from the lachrymal and salivary glands, is increased; and the pupil is contracted. It appears to paralyse the extremities of the motor nerves, in this respect resembling curare.

7. Curare is a resinous substance, containing an alkaloid, Curarin, of the composition $C_{16}H_{13}N$, obtained from certain parts of South America, and used by the natives of these regions as an arrow-poison. It is probably obtained from certain plants belonging to the genera *Strychnos* and *Paullinia*. Its distinctive physiological action is abolition of the power of all voluntary movement, in consequence of its action, as was proved by Claude Bernard, upon the peripheral terminations of motor nerves—the "terminal plates" of muscle. Respiratory movements are arrested in consequence of paralysis of the muscles of respiration, but the heart may continue to beat for a considerable time. If artificial respiration be established, the circulation may be maintained for several hours while the animal is completely under the influence of the substance. All the secretions are increased, and the mean temperature falls.

8. Muscarin, the alkaloid of *Agaricus muscarius*, causes arrest of the heart's action in diastole, an effect which may be removed by the influence of atropia, thus affording an instance of physiological antagonism. In warm-blooded animals muscarin slows the heart's action; the blood-pressure falls; respiration is first embarrassed, and may be completely arrested; parts containing involuntary muscle are in a state of tetanic spasm; the pupil is contracted; and secretion is increased.

9. Santonin, $C_{11}H_{15}O_3$, the alkaloid of *Artemisia santonica*, may cause in man nausea, vomiting, hallucinations, vertigo, and a peculiar state of visual sensation—the field of vision usually appearing yellow, but sometimes violet. It is said that the stage of violet rapidly passes into that of yellow, and therefore it is probable

that antonin may first excite the retinal fibres sensitive to violet (according to Thomas Young's theory of colour-perception), and afterwards paralyse them. In large doses, antonin causes loss of consciousness, tetanic convulsions, and death.

10. Ergotin, the active principle of *Secale cornutum*, causes contraction of the smaller blood-vessels, contractions of the uterus, and slowing of the pulse; and the animal may die in consequence of arrest of the action of the heart.

11. Quinia, $C_{20}H_{25}N_3O$, one of the alkaloids of Cinchona, in small doses accelerates the heart's action in the warm-blooded animal; in moderate doses it slows it; and in large doses it may arrest it, and cause convulsions and death. Research shows that its action is essentially upon the central nervous system. It destroys all microscopic animal organisms, apparently killing vibrios, bacteria, and amebæ; but it seems to be without action on humble organisms belonging to the vegetable kingdom. It arrests the movements of all kinds of protoplasm, including those of the colourless corpuscles of the blood. It arrests fermentive processes which depend on the presence of animal or vegetable organisms, but it does not interfere with the action of digestive fluids.

12. Cinchonin, $C_{20}H_{23}N_3O$, is said to have an action similar to quinia, but much more feeble. Further research is needed on this point.

JOHN G. MCKENDRICK.

ALOPECIA. See RALDWIN.

ALPHOS and **ALPHOIDES** (ἀλφός, white), terms signifying white and white-looking, are associated with the whiteness of the disks of common *Lepra*: hence *Lepra alphos* and *Lepra alphoides*. See *LMPRA*.

ALPHOSIS (ἀλφός, white).—Whiteness, or the process of turning white. See *ACHROMA*.

ALTERATIVES.—**DEFINITION.**—Medicines which gradually restore the nutrition of the body to a healthy condition, without producing evacuations, or immediately exerting any very evident action upon the nervous system.

ENUMERATION.—The principal alteratives are—Nitric and Nitro-hydrochloric acids; Chlorine and Chlorides; Iodine and Iodides; Sulphur and Sulphides; Potash and its salts; Mercury and its salts; Phosphorus; Hypophosphites; Antimony; Arsenic; Taraxacum; Sarsaparilla; Hemidesmus and Guaiacum; Mezerion and Dulcamara.

ACTION.—Healthy nutrition depends on the digestion of the food, its assimilation by the tissues, the decomposition of the tissues during the exercise of their functions, and the removal of their waste products being performed in a proper manner—in due proportion one to another. If the food is not properly digested, as in dyspepsia; or is not properly assimilated, as in diabetes; or if the tissues break up too rapidly, as in fever; or if the waste products are not properly removed, as in some cases of kidney-disease, nutrition suffers. Digestion and excretion may be improved by tonics, purgatives, and diuretics; but alteratives seem to exert their action upon assimilation and tissue-change. The digestion of food is effected by means of ferments, such as

those of the salivary glands, stomach, pancreas, &c. Some also of the changes, such as the conversion of glycogen into sugar, which the food undergoes after absorption in the liver, and even certain so-called vital actions—such as the coagulation of the blood—are produced by a similar agency. It is not improbable that the histolytic changes in the tissues are also effected by ferments. They do not depend upon oxidation, for although during health the products of tissue decomposition are oxidised as fast as they are formed, yet under certain circumstances the tissues are split up so rapidly that the products which they yield are only partially oxidised. This is seen in poisoning by antimony, arsenic, and still more markedly by phosphorus, where such tissues as the muscles become decomposed, yielding nitrogenous substances, such as leucin, tyrosin, or urea, and fat. The former are excreted in the urine; while the last, instead of undergoing combustion, accumulates in the place formerly occupied by the muscular tissue, which is accordingly said to be in a state of fatty degeneration. It is possible then, although by no means certain, that alteratives influence nutrition, either by modifying the activity of ferments, or by altering the susceptibility of the tissues to their action.

Mercurials in purgative doses, taraxacum, nitric and nitro-hydrochloric acids, probably act by modifying the digestion of the food in the upper part of the small intestine, or by affecting the changes which it undergoes in the liver after absorption. Potash has probably an action on the muscles. Antimony, arsenic, and phosphorus especially affect the nervous and cutaneous systems. Mercury has a peculiar power of breaking up newly-formed fibrinous, and particularly syphilitic deposits. Iodine, iodides, and probably chlorides, act upon the lymphatic system and promote absorption.

Urea.—Purgative doses of mercurials, taraxacum, nitric and nitro-hydrochloric acid are useful in cases of frontal headache, general malaise, and depression of spirits, associated with symptoms of so-called biliousness, or with the appearance of urates or of oxalates in the urine. Potash and colchicum are employed in the treatment of gout. Phosphorus and arsenic are used in cases of nervous debility, as well as in nervous diseases, such as neuralgia and chorea, in which antimony is also serviceable. Arsenic is also given in diseases of the skin; and antimony in inflammation of the mucous membrane of the bronchi. Mercury in alterative, that is, in small doses, which are absorbed into the circulation without purging, is used to break up newly-deposited fibrinous masses, as in iritis, pericarditis, &c., and to counteract the effect of syphilitic virus upon the soft tissues in the secondary stage of this disease. Iodine and iodides act on the lymphatic system, and are useful in removing glandular swellings. By stimulating the absorbent system they may also assist in the removal of the fibrinous deposits and syphilitic growths disintegrated by the mercury. The iodides are sometimes given in the secondary, but are still more valuable in the tertiary stage of syphilis.

T. LAUDER BRUNTON.

ALVEOLAR.—A word used in pathology as descriptive of any morbid growth which consists of small cavities or spaces (*alveoli*), usually occupied by contents, and bounded by walls formed of cells or fibres. Alveolar Cancer is the most familiar application of the term, being a synonym for Colloid Cancer. See CANCER.

AMAUKOSIS (*amaurosis*, dark).—DEFINITION. —This term cannot be strictly defined. Literally, it means an *obscurity of vision*, a state of *blindness*, in the popular sense of the term, whereby nothing more is learnt than that the patient cannot see well enough for practical purposes, and is thereby unfitted for the usual occupations of life. Besides this, it is always tacitly understood that an external observation of the organ of vision, during the life of the patient, does not reveal any ostensible cause of blindness. It is further understood that the use of glasses is no remedy in amaurotic cases. It is rather the kind, than the degree, of blindness that is called amaurotic, but it must be observed that lesser degrees of blindness, of the amaurotic type, are generally, vaguely and indefinitely, called *amblyopic*. To add to the obscurity of the subject, some writers call some cases of moderate blindness, of the amaurotic kind, *amaurotic amblyopia*; others speak of *partial* or *incomplete amaurosis*. We now estimate any defect of vision with more accuracy, and record its area on a map, and its degree in figures, in comparison with a standard of ordinary normal vision.

ETIOLOGY.—The causes of amaurosis have been more recently specifically attributed to morbid conditions of the percipient nervous apparatus of the eye or of vision. All cases are excluded in which, in the present state of science, and using the ophthalmoscope, we can see any morbid condition. But very few cases are now, in the statistical tables of the chief eye-hospitals, included under the head *amaurosis*. Some few cases seem likely, at least for some time to come, to be called by this term of reproach. The ophthalmoscope has enabled us more accurately to classify a large majority of the cases formerly called amaurotic. Many new names are thus introduced to our systematic treatises on eye diseases, whereby we gain more definite information, if only, as in some of them, e.g. 'white atrophy,' we have substituted the name of a particular ophthalmoscopic sign for an indefinite symptom. At least we can speak more accurately of the part that is or has been diseased—of the retina, or of the ocular end of the optic nerve. And, indeed, before the invention of the ophthalmoscope, the ancients, whilst professing to include only cases of disease of the percipient nervous apparatus of vision, included all kinds of obscure visual disorders. Mackenzie (1854) includes, besides retinitis, etc., choroiditis, and dislocated lenses! Of the first named he says, 'It would be superfluous to consider these states separately, because we are at present ignorant of any diagnostic signs by which, during life, the one can be discriminated from the other.' Even now, whenever the term amaurosis is had recourse to, it expresses more particularly that of which we are ignorant, and a may mean any one of so many different states that

so anatomical characteristics can be assigned to it.

In a large majority of the cases commonly classed as those of amaurosis, it is found ophthalmoscopically that there is 'white atrophy' of the optic nerves. The 'disks' are nearly or quite bloodless; white, not pinky-white; and the nerve-fibres going to the retina, being more or less wasted, there is some excavation of the disks, perhaps so much that the lamina cribrosa, in one or both, is exposed to view, while the retinal vessels are somewhat diminished in size. The causes of this condition are, most commonly, intracranial tumours or other diseases which induce pressure upon the optic nerve, or lead to an extension of inflammation, followed by oedema or double optic neuritis (descending), these terminating in the atrophy and amaurosis. The nerve-disease is often due to syphilis. But some cases of white atrophy occur, in which there has been no precedent neuritis. Of such 'tobacco amaurosis' is an example, in which, unless smoking be given up, by an idiosyncrasy of the patient, he soon becomes blind. But nerve-atrophy or inflammation should be no longer called amaurosis—they have obtained a better nomenclature. The preceding stages of the diseases causing them, if, as is rarely the case, unaccompanied by any definite ophthalmoscopic signs, and yet producing a considerable amount of blindness, may, for want of better knowledge, at present be called *amaurotic*. Other such cases are those reported as snow-blindness; or in which blindness has been produced by a lightning-flash near the eye, a blow on the eye without other mischief resulting; disuse of an eye in children, as in some neglected squint cases; irritation from some branches of the fifth nerve (dental caries, etc.), anemia after excessive losses of blood; suppression of menses; blood-poisoning by tobacco, lead, quinine; uræmia; and some cases of cerebral apoplexy. Embolism of the central artery of the retina occurs, but it is easy of diagnosis with the ophthalmoscope, and therefore should not be called amaurotic. The writer does not think there are any cases of *long-standing* blindness that show no ophthalmoscopic changes.

SYMPTOMS AND DIAGNOSIS.—There is one symptom of amaurotic blindness, affecting both eyes, which is noteworthy, as constituting, *primæ facie*, a general distinction between it and the other cases of blindness *not* of nervous origin: the quit and general aspect of the patient is peculiar—he is hesitating and hopeless-looking. He no more *tries* to see objects. He holds up his head; the eyes are open and turned upwards, as eyes not in use (or sleep) always are, or because the patient has felt the heat of the sun from overhead, and has last enjoyed sensation of light, whence he knows it comes, from above. He feels his way with his feet, and his hands are extended before him. He does not look towards you, or at anything in particular. But amaurosis does not by any means imply a similar state of vision in both eyes, nor that the blindness is to be taken in the ophthalmological sense, i.e. wanting perception of light. It would be well if any less degree of imperfection of vision, without evident change,

might be called *amblyopia*, but the two eyes must be considered separately. To diagnose the absence or presence of a power of perception of light, certain important precautions must be taken, as almost all patients who are absolutely blind will declare, and probably believe, that they still can see light, i.e. objective light. The patient should be placed opposite to a bright light, such as a gas-lamp, and near to it, but not so near that he can feel the heat of it: the light is then turned up and down, and it is fully exposed and obscured, and the patient is asked many times, in quick succession, if he sees light or not. The light should be left burning and exposed, or not, during several of the successive queries, so as to do away with any doubt. The word of the patient untested is quite inadmissible. Any other blindness than this of absolute amaurosis, or originating in any other diseases than those of the percipient nervous apparatus of the eye, is never so great as to prevent the perception of light. If the patient can see light from darkness, test whether he can see shadows of some small object—of the hand, or of one finger only, passed between him and the burning light, or the light of the window only. If he can see to count fingers, his blindness is insufficient to indicate what is called amaurosis. Another point in the diagnosis of amaurosis is that, ophthalmoscopically, the appearance of the fundus of the eye is normal, or such as, independent of errors of refraction, we find in other cases compatible with standard vision, or at least with a fair amount of useful vision. This will allow of a considerable latitude, and will not include any slight or imaginary hyperæmia or anemia of the optic disk, any physiological excavations of the same, or congenital opacities of the retina, etc. The pupil of the affected eye is, if the other be perfectly excluded from light or vision, nearly always dilated, to almost the greatest extent, though atropine dilates it yet more fully, and it is fixed, being insensible to light.

PROGNOSIS.—After a due consideration of the cases thus classed together—and they are very unlike in fact, and often very obscure—we may say generally, that if the blindness be of one eye only, sudden and recent, the prognosis is hopeful; but if both eyes are affected, and the disease, whatever it may be, is of steady progress and of long standing, it is very serious. The cases of amaurosis are very rare indeed in which vision is perfectly restored; most of them end fatally to vision, or would so end but that the disease is sooner fatal to life.

TREATMENT.—This must necessarily be varied according to the cause of the amaurotic condition. For instance, if there is intra-cranial disease, treatment directed thereto must be followed out; and should there be indications of syphilis, iodide of potassium and small doses of mercury must be given for some time. When amaurosis depends on any injurious habit, such as smoking, this must be relinquished. Large doses of strychnine and iron are useful in advanced white atrophy. J. F. STREATHFORD.

AMBLYOPIA (ἀμβλῆ, blunt, and ὄψις, sight).—Obscurity of vision. See AMAUROSIS.

AMBULATORY (*ambulare*, to walk).—A term applied to latent typhoid fever, signifying that the patient is able to walk about during the attack. See **TYPHOID FEVER**.

AMENORRHOEA (ἀ, priv.; μῆν, a month; and ῥέω, I flow).—Absence of the menstrual flow during any portion of the period of life when it ought to be present. See **MENSTRUATION**, Disorders of.

AMENORRHOICAL INSANITY. See **INSANITY**.

AMENTIA (ἀ, priv., and μέν, the mind).—An obsolete term for Dementia. See **DEMENCIA**.

AMNESIA (α, priv., and μνήσις, memory). See **APHRASIA**.

AMPHORIC.—A peculiar hollow metallic sound, elicited occasionally by percussion, but more commonly heard in auscultation. Amphoric breath-sound resembles that produced by blowing into a large empty glass or metallic vessel (*amphora*). See **PHYSICAL EXAMINATION**.

AMYGDALITIS (*amygdale*, the tonsils).—A synonym for inflammation of the tonsils. See **TONSILS**, Diseases of.

AMYLOID DISEASE (ἀμυλον, starch).—The name given by Virchow to Albuminoid Disease, from the belief that the material characteristic of this morbid condition is of the nature of starch or cellulose. See **ALBUMINOID DISEASE**.

ANÆMIA (ἀ, priv., and αἷμα blood).—**SYNON.**: *Spanæmia*; *Hydræmia*; *Oligæmia*, *Aglobulism*. Fr. *Anémie*. Ger. *Anämie*, *Blutar-muth*.

DEFINITION.—Deficiency of blood in quantity, either general or local; also, deficiency of the most important constituents of blood, particularly albuminous substances and red corpuscles.

This definition is purely pathological, and the condition thus expressed presents many varieties. Anæmia in the widest sense of the term including Oligæmia, Oligocythæmia, Hydræmia, and Spanæmia, as well as Chlorosis. (See **CHLOROSIS**, **HYDRÆMIA**, **SPANÆMIA**, **OLIGOCYTHÆMIA**, and **BLOOD**, Morbid Conditions of.) From the clinical point of view, Anæmia is a condition of system in which impoverishment of the blood, whether from want or from waste, is associated with symptoms of imperfect discharge of the vital functions.

ÆTIOLOGY.—The causes of anæmia are generally multiple and complex. First, the supply of blood to the body may be insufficient, and that from a variety of causes, of which the chief are:—derangements of alimentation, including insufficient food, and morbid states of the lymphatic and blood-glands; such defective hygienic conditions affecting the formation and nutrition of the blood as want of light, air, and muscular exercise; prolonged exposure to the influence of certain poisons, as lead, mercury, and malaria; and, lastly, interference with the free circulation of the blood by cardiac or vascular disease, such as valvular disease or dilatation of the heart and anæmia of the aorta. Secondly, the consumption of blood may be increased by hæmorrhages; by profuse discharges, such as suppura-

tion, catarrh, and albuminuria; by rapid growth and development; by frequent pregnancy and superlactation; by excessive muscular exertion, and by the presence of pyrexia, or of new growths, which rob the system of nutritive material. In a third group of cases of anæmia both the supply and the consumption are at fault. Thus derangement of the organs and of the whole process of sanguification is frequently associated with profuse discharges from various parts; and in malignant diseases and the 'chronic constitutional diseases,' such as syphilis, tuberculosis, Bright's disease, albuminoid disease, Addison's disease, and others, the cause of the anæmia is extremely complex. But the majority of the cases of anæmia that are regarded and treated as such fall into the class to which the name of *subpænic* has been applied. In such cases the anæmic condition is due, not to any disease so-called, but to disturbance of nutrition generally, that is of the healthy relation between the demands of the system and the supply of nutrient material. This condition occurs chiefly in children and young women, at the period of bodily growth and of the development and early activity of the sexual functions; and when, as so frequently and unfortunately happens, the air, light, food, occupation, and moral relations of the individual are all more or less unhealthy.

ANATOMICAL CHARACTERS.—The blood suffers three principal changes in declared anæmia, namely, (1) deficiency in amount (*Oligæmia*); (2) deficiency in red corpuscles or hæmoglobin (*Oligocythæmia*, *Aglobulism*), and (3) deficiency in albuminous constituents (*Hypalbuminosis*). Of these *Oligæmia* is the simplest, and perhaps never occurs alone, it is speedily complicated with *Aglobulism*, which is a very early and common, as well as the most ultimate, change in the blood. *Hypalbuminosis* is the most advanced and perhaps the most serious alteration of the three. (See **BLOOD**, Morbid Conditions of.) The blood is scanty and pale, and has a diminished specific gravity; and coagulates slowly and loosely, or in aggravated cases not at all, settling into three layers—consisting respectively of red corpuscles, white corpuscles, and plasma. The body presents certain changes directly due to the state of the blood. Whether the anæmia be local or general, the corresponding parts are blanched and 'bloodless.' The cells of the tissues become atrophied and degenerate, in consequence of, and in proportion to, the interference with their plastic and functional activity respectively, and the so-called 'anæmic' form of fatty heart, liver kidneys, and other organs, is the result. If death occur suddenly from acute anæmia the heart is found empty and contracted.

PATHOLOGY.—When the volume of blood in the body has been reduced by repeated small hæmorrhages, the phenomena that supervene, while they express the want of blood as a whole, and of its several constituents, are chiefly referable to the loss of two of these constituents—the albuminous substances and the red corpuscles or hæmoglobin—that is, of the oxidisable and the oxidising materials. The pathology of hypalbuminosis and aglobulism is fully discussed in the article on diseases of the blood, and need not be

repeated here. The same effects will be produced by a drain of the liquid part only of the blood, or by poverty of the blood from any of the causes enumerated above, whether of the nature of waste or of want; inasmuch as loss of plasma speedily affects the nutrition of the red corpuscles. These phenomena constitute the symptoms of the anemic condition whatever may be its cause; their relative prominence naturally varying according to an immense number of circumstances.

SYMPTOMS.—The subjects of anemia are usually girls and young women. Their general appearance, which is striking, is one of pallor, debility, and variable loss of feminine fulness. The visible parts of the surface are pallid, often with a tinge of dusky brown on the eyelids and the backs of the hands, the clearness of the complexion varies with the normal pigmentation of the body; the skin is soft, satiny, and rather loose. The mucous surfaces also are blanched; the sclerotic is pearly blue. The loss of flesh may be moderate, or it may be considerable. The extremities are cold, and the legs and lower eyelids are often œdematous. Bodily strength is reduced; muscular force is diminished, while myalgia is common; an air of languor and want of vigour pervades the whole demeanor; and the patient is sleepy, dull, and depressed. The subject of anemia generally complains of weakness, various pains about the body and head, and marked shortness of breath on the least exertion. The last symptom is unaccompanied by other evidence of respiratory derangement; in character the breathing is regular, and short or even panting. The symptoms referable to the circulation consist chiefly of palpitation on exertion; a tendency to faint; and pain or even distress over the cardiac region. The impulse is variable; the first sound is either hollow or murmurish, or converted into a murmur at the base, and frequently even over the whole præcordium; the diastolic sound is sharp generally. Over the manubrium and in the cervical vessels a murmur followed by a sharp sound is commonly audible, and therewith a venous hum. The cervical vessels may throb; the radial pulse is small, soft, weak, and of variable but usually increased frequency and suddenness. There is a tendency to hæmorrhages, especially epistaxis; and petechiæ are occasionally observed. The digestive system is markedly affected, as shown by loss or perversion of appetite; an anæmic, often bare, but variable tongue, dyspepsia, nausea, and sickness after meals or on rising; and constipation, which is present in the majority of cases and is frequently prolonged and severe. The menstrual functions are almost always deranged; amenorrhœa is common in some form; menorrhagia is rare (except as a cause of anemia); dysmenorrhœa is frequently associated; and leucorrhœa is the rule. The urine is usually abundant and pale, but varies greatly. Headache and other cerebral symptoms are common. Blood drawn from the finger presents agglutination. See HÆMAGTOMETER.

The leading phenomena of *acute* anemia are those of syncope, or suspended animation from failure of the circulation, and are described under that title.

• **COURSE AND TERMINATIONS.**—The course of

anemia in this form is essentially slow and progressive, unless it is checked; the duration is perfectly indefinite. The course of the symptomatic form will naturally vary with its cause. Idiopathic anemia rarely terminates fatally; and, when it does so, the event may be referred with few exceptions to some complication. Occasionally, however, it proceeds steadily to death (see *PROGRESSIVE PERNICIOUS ANEMIA*, below).

Intercurrent diseases may be expected to be severe in an anæmic condition, in proportion to its degree.

DIAGNOSIS.—Anemia is generally recognised with the greatest ease, and the chief question of diagnosis relates to its cause. The first point to be determined, therefore, is whether it is not *symptomatic* of some more grave state, such as tuberculosis, syphilis, albuminoid disease, or some other of the many possible causes of poverty of blood. Having settled that the anemia is *idiopathic*, we must next exclude two diseases with which it may be confounded, namely, chlorosis and leukemia. Chlorosis, in which the plasma is not considered to be altered, and which possesses otherwise a special pathology, is expressed by the yellow tint of skin, by the absence of wasting and of dropsy, as well as by other features (see *CHLOROSIS*.) Leukemia is recognised by examination of the blood, spleen, and lymphatic glands. The starting-point of the blood-change in cases of idiopathic anemia, can only be discovered by careful investigation of all the facts of the case.

PROGNOSIS.—The prognosis of anemia is favourable as regards life. In simple anemia from loss of blood, the patient may be assured of speedy and complete recovery. In idiopathic anemia, however, this promise can be given only when the cause can be removed or avoided. Under favourable circumstances and sound treatment, improvement will begin almost immediately; and health should be restored after a few weeks or months.

TREATMENT.—The treatment of anemia, when it is symptomatic of some more grave condition, such as Bright's disease or phthisis, does not require notice here. When blood has been lost in serious quantity, without other injury of consequence, it will be naturally restored if sufficient time but be given and interference otherwise avoided. Attention to the ordinary rules of health, abundance of food and air, and moderate exercise, will surely, if slowly, restore the patient, without the administration of a single drug. Even in this case, however, treatment may be of great service, by arresting, if necessary, the cause of the anemia, such as menorrhagia or epistaxis; and by assisting nature, if the condition should threaten at any time to become intensified by its own effects.

But before the blood can be restored in the large and ill-defined group of cases known as idiopathic anemia, the unhealthy influences under which the patient is placed, and the functional and other derangements, which are usually accountable for the imperfect sanguification, must be discovered and corrected. Where the etiology is complex, treatment must be equally general, and the whole system of life will have to be regulated. On the other hand, in the rapidly growing anæmia

and youth, and still more in girls at puberty, the great demand for nutritive material must be duly considered and every obstacle to its supply removed. When other than direct discharges are draining the blood they must be checked. Lactation may have to be forbidden; and leucorrhœa and spermatorrhœa will sometimes demand local treatment.

The removal of the cause being thus made the first element in treatment, means must next be adopted for the restoration of the blood. But before this can be accomplished, it will be necessary to bring the alimentary tract and the organs of sanguification into a healthy state. Dyspepsia and constipation require immediate treatment; and for this purpose simple alkaline and bitter stomachics with rhubarb, and free purgation by ordinary means, followed by a course of aloes and iron pill at night, are the best. The food must be carefully ordered, so that it shall not only supply the albuminous elements that are specially deficient in the blood, but be retained and absorbed; it must therefore be at once nourishing and digestible, and be taken in small quantities at frequent intervals. The patient must not be allowed to yield to the disgust that she may have for meat.

The process of sanguification may be successfully assisted by means of drugs. Iron is the sovereign remedy for aglobulism, and, practically speaking, it speedily becomes a question in the treatment of a case of anæmia in what form iron is to be given. The compound iron mixture of the pharmacopœia answers more frequently than any other; but, on the one hand, when there is much constipation, the proto-sulphate with purgative saline sulphates will be more suitable for a time; and, on the other hand, when there is a tendency to discharges, the per-salts with bitters will better answer the purpose. The combinations of iron with quinia or strychnia, should be given in cases where less marked anæmia occurs in older subjects with nervous depression and general want of vigour. In special cases the ferrum redactum, saccharated carbonate, vinum ferri, or the French *dragées ferrugineuses* at meal times may be ordered. Cod-liver oil may sometimes be prescribed with success. Other symptoms must be treated on ordinary principles. Uterine complaints demand special attention; and bromides, ergot, opium, and other sedatives and astringents are indicated where excitement and excessive discharge are present. While these dietetic and medicinal measures are being carried out, it is impossible to insist too strongly upon attention to bodily and mental hygiene. In a large number of cases change of air fulfils all the necessary conditions, and it is generally to be recommended. Above all, time is an essential element in the cure; and rest is scarcely less so. A frequent change in the form of the medicinal remedies is also advisable.

Progressive Pernicious Anæmia.—A peculiar form of anæmia has long been known, but has lately attracted special attention, and is variously designated as *pernicious*, *malignant*, *asthenic*, and *progressive*, on account of the intensity of the symptoms, the obscurity of its ætiology, and the frequency with

which it advances to a fatal termination. This disease may occur in both sexes, but has been most frequently observed in middle-aged, pregnant women; it presents no special post-mortem appearances; and it cannot be referred to any reasonable cause. The symptoms are those of excessive anæmia, as described above; but gastric disturbance and general hæmorrhages are relatively prominent, and, in some cases, irregular attacks of pyrexia occur. The blood during life is said to differ from that found in ordinary anæmia, by containing an unusual amount of ill-shaped red corpuscles and granular matter. The course of the disease is steadily towards death, in which it generally terminates. The pathology of progressive pernicious anæmia is obscure. It is believed by some to be but the advanced stage of ordinary anæmia, which attracts attention by its resistance to treatment, and its fatal termination. The appearance of the blood would seem to indicate excessive destruction, rather than insufficient supply of the important elements, as the essential cause of the morbid condition; but there is probably derangement in both directions. The prognosis is as unfavourable as possible. Treatment must be ordered on general principles: transfusion has been frequently tried, but without success.

J. MITCHELL BRUCE.

ANÆMIA LYMPHATICA.—A form of Anæmia which is associated with a peculiar affection of the Lymphatic System. See HODGKIN'S DISEASE.

ANÆSTHESIA (ἀ, priv., and ἀναισθημα, I feel).—Anæsthesia literally means absence or loss of sensation, which may be general or local. The word is, however, more especially employed to signify loss of tactile sensibility, as distinguished from insensibility to pain or *Analgesia*. It is further used to indicate the condition induced by the action of Anæsthetics upon the system. See SENSATION, Disorders of.

ANÆSTHETICS.—DEFINITION. The name given to a series of agents which are employed for the prevention of pain, but more especially applied to those used in surgical practice.

HISTORY.—The idea of annulling pain in surgical operations is a very old one. Compression of the nerves and blood-vessels, and the inhalation of the vapour of mixtures containing carbonic anhydride were practised at an early date. In the sixteenth century ether was probably the active ingredient of a volatile anæsthetic described by Porta. The use of anæsthetics was, however, but little understood and rarely practised. Even the suggestion of Sir Humphry Davy, that nitrous oxide should be used in minor operations not attended with loss of blood, was of little practical value, on account of the inefficient apparatus then available. In 1845 Horace Wells inhaled laughing gas so successfully that he may be said to have introduced the practice; but he appears to have so often failed to produce the desired effect that this agent fell into disuse on the introduction of ether in 1846 by Morton, after some communication on its properties from a chemist named Jackson. In 1847 chloroform was used by Simpson, and quickly superseded ether almost all over Europe. At the present

time the comparative safety of ether has caused this anæsthetic again to be preferred by many surgeons in this country.

EXUMERATION.—The three agents just mentioned, namely, nitrous oxide, ether, and chloroform, are those chiefly in use, and they have each advantages in particular cases. Experiments made with other agents such as amylene, tetrachloride of carbon, ethiodichloride, and bichloride of methylene, have not shown that they possess sufficient advantages to counterbalance the defect of requiring special management in their administration. This list of anæsthetics might be still further increased, for in order to produce immobility it is only necessary to reduce the supply of arterialised blood to the nervous centres, or to introduce into the blood a substance which deprives it of its power of oxygenating the tissues.

MODES OF USE.—Anæsthesia may be produced for surgical purposes:—1. by benumbing the part to be operated on by means of cold, 2. by intercepting its nervous communication; 3. by arresting the activity of the nervous centres concerned in sensation. Thus anæsthetics may be *local* or *general* in their action.

Local Anæsthesia may be induced by cold. The most convenient plan is to blow a jet of anhydrous ether spray upon the part, as suggested by Dr Richardson, and thus to freeze it. The surface to be frozen should be dry, and hence the difficulty of freezing the gum of the lower jaw, on account of the saliva. A mixture of equal parts of pounded ice and common salt contained in a bag of muslin is effective, but less easily applied. This plan is adapted for opening abscesses and boils, and for the extraction of a few teeth; but the process both of congelation and of thaw is painful. Chloroform applied locally is said to cause numbness, but it is very little used except inside the mouth, and then it owes its soothing effects to the quantity of chloroform vapour which is inhaled. Compression of nerve trunks for inducing anæsthesia is never practised at the present day.

General Anæsthesia is at present rarely obtained in any other way than by inhalation, although successful attempts have been made to induce the condition by subcutaneous and intravenous injection of chloral or morphia.

SUBJECTS FOR ANÆSTHETICS.—We may say generally that any person fit for a severe operation is a fit subject for an anæsthetic, but no one is so free from danger that care in watching its effects can be dispensed with. The cases requiring the greatest vigilance are not the young and delicate, for whom a small dose suffices, but the strong, who inhale deeply and struggle much. Ether is probably better for those suspected of fatty degeneration of the heart, although as a rule such cases are eminently satisfactory under chloroform. Many of the deaths under chloroform have occurred in intemperate drinkers, and the presence of alcohol in the system undoubtedly intensifies its effect.

PRECAUTIONS.—Before commencing inhalation the following particulars should be attended to. The patient must not have recently taken a full meal: he should lie comfortably, in a horizontal position if possible, unless when gas or ether is

given for a short operation; and the dress should not be tight. When the administration is begun, he should be encouraged to breathe regularly and freely. The pulse as well as the respiration must be watched. If the vapour excites either swallowing or coughing, it is more pungent than is requisite, and its strength should be diminished. Most patients are at first afraid of breathing, and some hold their breath for half a minute. The vapour should not be removed on this account, but care should be taken, by holding the inhaling apparatus farther off, to prevent the vapour becoming too strong in the interval. After volition has been abolished, any pause in the breathing should be noted, and more or less fresh air given. Further directions will be given in describing the anæsthetics specially.

SPECIAL ANÆSTHETICS.—*Protaxide of Nitrogen, Nitrous Oxide, or Laughing Gas.* This agent is now prepared wholesale, and sold condensed in a liquid in strong iron bottles. The gas, whether supplied thus or from a gasometer, should be inhaled from a bag having such a free communication with the face that it will readily be supplied even in panting respiration. A long tube, however large, is objectionable, as the gas is less mobile than common air.

The special aim in giving gas should at first be to exclude air, and to exchange the atmosphere within the air-passages and lungs for one of pure gas. The patient should not merely be told to breathe slowly and deeply, but be shown how to do so, about fifteen times in a minute. The inspiration should not be jerking, and the expiration should be complete. It is a special merit of laughing gas that no harm can come of inhaling too freely at first. The gas-bag must be kept filled either by pressure on the gasometer, or by turning the screw tap of the gas bottle. This may be done by the hand of an assistant, or more conveniently with the foot of the administrator, by means of a contrivance invented by Mr. Brains, in which the gas-bottle is placed horizontally upon rollers and moved by the foot whilst the head of the screw is fixed. The writer's plan is to fix the bottle vertically and turn the screw by pressing the foot against an iron plate with spikes on its upper surface, and a square hole fitting the tap on its lower surface. It is imperative that the face-piece or mouth-piece should fit accurately, and the air-pad is almost essential to effect this in a great many cases. It should be warmed if the india-rubber is stiff. After five or six good respirations there is no need of supplying fresh gas with each inspiration. The expiring valve should be kept closed, and the inspiring valve opened. Care must always be taken that the supply of gas is sufficient to replace any that is lost by absorption into the blood or by leakage. This is more easily effected if the gas-bag is made of thin india-rubber, so as to distend easily and contract gently with the movement of breathing. It should be sufficiently filled, so that if the mouth-piece does not fit, the gas would escape instead of entering and becoming mixed with it.

Lividity of the skin will not help us to know when the patient is fully under the influence of the gas, neither will insensitiveness of the pupils, nor yet the state of the pupils. The breathing

should become stertorous or interrupted, or the pulse very feeble, or convulsive twitchings should occur, before the face-piece is removed. A little air may be admitted by raising the face-piece, if the operation is not upon the face, and by doing so every fourth or fifth respiration anaesthesia may be kept up for several minutes. The effect of a single full inspiration may be to bring the patient into a state of excitement, and the continuance of the gas *without* air brings on convulsive movements so that it is not well adapted for any operation lasting as much as five minutes, and requiring steadiness.

Patients are sometimes so unsteady that it is found to be almost impossible to make the face-piece fit. In such cases the best plan is to cover the patient's eyes and let him breathe air, merely preventing him from rising from the chair or bed, and not speaking till he is conscious, and as soon as he becomes so to recommence the inhaling as if nothing had happened. A violent patient often becomes perfectly rational in less than two minutes.

Sickness and headache ought not to result from the inhalation of gas, but if the use of it is prolonged, or if the patient is kept for several minutes in a semi-conscious state, breathing a little air with the gas, both these symptoms may occur. The recumbent posture, quiet, and warmth to the feet, constitute all that is likely to be required in the way of treatment.

Ether, Sulphuric Ether, Ethylic Ether, Vinic Ether, or Oxide of Ethyl, was first used for anæsthetic purposes in 1846. Before its use was well understood in England chloroform was brought forward as a more convenient agent, and much less unpleasant to the patient. Ether is less liable to become dangerous to life, as it does not under ordinary circumstances depress the action of the heart.

If ether be given from a towel or hollow sponge, the best kind is the *Æther Parvus* of the Pharmacopœia, of sp gr. 720; but the ether of sp gr. 735, which contains a little water, answers very well if the towel or napkin is arranged so as to form a large cone, thus lessening the access of fresh air. The disadvantage of using the latter kind is that the moisture of the patient's breath condenses upon the surface made cold by the evaporating ether, and diminishes its volatility. When pure ether is used, a certain amount of condensed aqueous vapour is taken up before it reaches the density 735.

In all inhalers where an arrangement is made for preventing the ether from becoming too cold, the washed ether 735 may be used, and will be found cheaper. Not only is it sold at a lower price, but it is much easier to keep from escaping through cork or stopper.

Although it is not difficult to destroy dogs suddenly with ether, it is believed by many writers on the subject that in man it can only prove fatal by causing asphyxia, and that the signs of this condition are so easily seen and remedied that practically this anæsthetic is quite safe. The writer is not of this opinion, believing that sometimes when narcosis is far advanced, the glottis will allow ether vapour to pass of sufficient strength to stop the heart. Such cases, however, are very rare indeed. Ether is extensively adminis-

tered by pouring an ounce at a time upon a very large cup-shaped sponge, which, if cold from previous use, is dipped into hot water and squeezed as dry as possible. It is to be expected that the patient will resist breathing when this is held over his face, but after a minute's struggling he becomes unconscious, and easy to manage. Compared with giving ether timidly, so as to let the patient remain delirious for several minutes, this may be a good plan; but there is no necessity for giving the ether so strongly if we diminish the access of fresh air. The admixtation of nitrous oxide from which air is at first excluded, and afterwards admitted very sparingly, has taught us how slight the after-effects are from the asphyxia so induced. Cones of leather or paste-board lined with felt, and having a small opening at the apex, are better than sponges, but they should be larger. They may be made more effective and economical by placing a thin india-rubber bag over the apex of the cone, so that more of the expired atmosphere may be breathed again.

Morgan's inhaler is very efficient. The ether is poured into a tin chamber as large as a hat, containing sponge. This is covered by a sort of diaphragm, which rises and falls with respiration as the patient breathes into and out of it by means of a tube and face-piece. There are no valves. Anaesthesia results partly from asphyxia, and partly from the action of the ether. The amount breathed depends on its temperature, and on the freedom of respiration. If the respiratory movements are slight, as in young children, or in persons suffering from emphysema, the amount of ether supplied is apt to be too small. Ormsby's inhaler is an improvement upon it. The sponge for ether is contained in a cage near the face-piece.

An excellent inhaler for hospital purposes and for prolonged operations is sold by Mr. Hawkey. The ether vessel is kept in a water-bath. There are valves which allow air to pass over the ether, but prevent its return, and the apparatus has an arrangement for lessening the odour of ether in the room, consisting of a tube leading to the floor, which carries off the expired air and ether.

With the view of regulating the strength of the ether vapour, the writer has contrived the following apparatus, which is made by Mayer and Meltzer. It consists of an oval india-rubber bag fifteen inches long, at one end connected with the face-piece, at the other with the ether-vessel. Within the bag is a flexible tube also leading from the face-piece to the ether vessel. By turning a regulator the patient is made to breathe into the bag either directly or indirectly through the tube and ether vessel, or partly one way and partly the other. The more the regulator is turned towards the letter E, the more ether vapour he takes. By turning it back again the amount of vapour is diminished. The ether-vessel contains a reservoir of water, which prevents the ether becoming too cold from evaporation. It is filled with ether up to a mark on the vessel. A thermometer in connection shows the temperature of the ether. The vessel should be just dipped into a basin of warm water and gently rotated till the thermometer reaches from 60° to 70°.

When used this vessel should be suspended by a strap from the neck of the administrator.

At first the regulator allows the passage from the face-piece into the bag to remain open, and the bag should be filled by pressing the face-piece more firmly against the face during expiration than inspiration. By degrees the regulator is turned towards letter E, and thus the way to the inner tube is opened, and the air breathed through it carries ether vapour from the vessel into the distal end of the bag. When the regulator allows half the inspired air to pass through the ether, the vapour is strong enough to induce sleep in two minutes, usually without exciting cough. As the act of swallowing is excited by a smaller quantity of ether than that of coughing, it should be watched for, and the regulator very slightly turned back should it occur.

This same apparatus may be used for giving laughing-gas, and communication with the ether-vessel being cut off by turning a stopcock, and by attaching the tube leading from the gas-bottle to a mount near the bag.

By far the least unpleasant and the quickest way of preparing a patient for a surgical operation is to use gas and ether combined; the change from gas to ether being made by turning the regulator above described as soon as the patient is sufficiently under the influence of gas to disregard the flavour of ether. The supply of gas should be stopped as soon as the ether is introduced, but it subsequently the patient is allowed to become conscious, the gas may be given freely as at first, in order to make him sleep again. The writer finds less sickness and more rapid recovery from the unpleasant taste of ether than when the latter is given alone. The chief difficulty is to prevent the uneasiness of the patient, resulting from the panting character of the breathing. To lessen this the ether must be given as strong as possible without producing irritation of the throat, and the operator should wait until the influence of the ether has increased to the production of deep stertor. Air being then admitted with every fourth or fifth inspiration, the breathing soon becomes as regular as it is under ether when given in any other way.

On recovering from the inhalation of ether patients are often in a state of intoxication for a period corresponding to the time and extent of the etherization. The eyes should be covered, but the mouth and nose left free, and the room should be kept quiet, with a brisk fire, and the window more or less open. See APPENDIX.

Chloroform was introduced by Simpson in 1847. It should not be made from methylated spirit, and, when a drachm is poured upon blitting paper, it should evaporate without leaving an unpleasant odour. It is the most convenient of all anæsthetics, and the most easy to administer. Unfortunately, when given beyond a certain strength, it has a tendency to produce curdlike syncope, and it is not improbable that nervous persons are particularly liable to be so affected.

Some authorities think it desirable to give alcoholic stimulants before administering chloroform; others partially narcotize the patient with morphia or chlorid. No doubt these agents assist the action of the chloroform, but if from any

accident an excess of chloroform should be given, they interfere with the means of recovery, and for this reason are not to be recommended. There is less objection to the inhalation of a mixture of chloroform and ether, or of these agents with alcohol; but such mixtures, if kept for some length of time, alter their relative proportions, owing to the escape of the more volatile ingredients. Even the change from the administration of chloroform to that of ether, if made suddenly, is not free from danger, for, when a person is partially under the influence of chloroform, the glottis allows a high percentage of ether to pass, and, if the lung-circulation be slow, as is likely to be the case, the blood may be so highly charged with ether as to depress rather than stimulate the heart.

Chloroform, therefore, should be given gradually. The object should be to keep down the proportion of chloroform-vapour rather than to give abundance of fresh air. In preparing for an operation requiring perfect stillness, six to eight minutes should be allowed for the process. Sponges or lint saturated with chloroform, and held close to the mouth, are dangerous, from the possibility of liquid chloroform falling on the lips or into the mouth. In midwifery practice a piece of linen or blotting paper sprinkled with chloroform and placed at the bottom of a tumbler is a convenient plan of administration, care being taken to prevent any liquid chloroform from settling at the bottom. In general surgery a handkerchief or towel may be folded into a small cone, upon at the apex, into which not more than a drachm should be poured at first, and fifteen minutes at a time afterwards. A better plan is to roll and tie a piece of lint into a compress the size of a walnut. A drachm to a drachm and a-half of chloroform should be poured upon this, which is to be held about an inch in front of the patient's upper lip, the hand and compress being covered with a towel, which should gradually be drawn over the patient's face. This plan gives considerable command over the supply of chloroform, for, when the chloroform, having cooled by evaporation, is given off too slowly, the vapour can be increased by warming the compress in the palm of the hand. When it is becoming dry it ceases to feel cold, and warning is thus given that fresh chloroform is needed. This should be supplied half a drachm at a time. In doing this the towel should still be left over the face of the patient in order to keep him breathing a slightly chloroformed atmosphere. The movement of swallowing should be looked for, and regarded as evidence that the vapour is stronger than is necessary. If any sound like liccough indicates laryngeal obstruction, the chloroform and towel should be removed, and, if the sound continues, the chin should be raised as much as possible from the sternum. Laryngeal obstruction arises from two main causes, viz., spasm of the glottis, and falling down of the epiglottis. The first is excited by the pungency of the vapour, and also by reflex action when certain nerves are injured, notably when a ligature is tightened upon a pile. The epiglottis covers the larynx every time we swallow, but the muscles coming from the chin raise it again directly. In doing

narcosis these muscles are sluggish, and cannot act thus if the position of the chin places them at a disadvantage. If raising the chin fail to open the air-passage, the tongue must be pulled forward. In doing this the head should be kept back. Depressing the chin renders a partial obstruction complete. A laryngeal sound indicating obstruction is of little consequence if the pulse is good, since, although the breathing be imperfect, sufficient fresh air continues to be breathed; but if the pulse flags, or if it appears that the amount of chloroform in the air-passages is excessive, not a moment should be lost in seizing the tongue with forceps.

When a patient is delirious and struggling, extra care must be taken that the chloroform be not too strong, because he inhales deeply, carrying the vapour almost to the air-cells of the lungs, and, when he next closes the glottis and strains, the pressure of the air and vapour within the lungs is increased, and the chloroform enters the blood very quickly. The compress should be held at least two inches off the mouth, although the towel may still cover the face. Directly any stertorous noise is heard, a breath or two of fresh air should be allowed, and no more chloroform given till the pulse beats well and the respiration is free.

Skinner's apparatus—a cap of 'domette' flannel stretched over a frame—is a much better apparatus than a towel; but its virtue is simplicity, and it has little pretension to exactitude. Snow's apparatus is very efficient, portable, and economical. The addition of a water-jacket to equalize the temperature was a great improvement; but it should be provided with a thermometer.

The safest and least unpleasant mode of giving chloroform is by means of the apparatus fitted with a large bag of air containing not more than thirty-three minims of chloroform in a thousand inches of air. The apparatus is, however, too complex to be generally adopted, and the writer hopes shortly to be able to introduce a modification of it which will be more easily used. The advantage of more precise measurement of the strength of chloroform-vapour than is afforded by towels or napkins will appear when we consider the several circumstances that alter it when so given.

The *strength of vapour* given off from a known quantity of chloroform is influenced by:—

1. The extent of surface of chloroform.
2. The temperature of the chloroform, which is constantly changing.
3. The temperature of the air of the room, of the patient's face, and of the administrator's hand.
4. The distance at which the chloroform is held from the patient's face.
5. The rapidity of the current of air.
6. The height of the barometer.

Moreover, when the chloroform-mixture is of known strength, its effect is increased by high barometrical pressure; by low temperature of the blood: by deep or quick respiration, and especially by muscular efforts when the glottis is closed; and by slow movement of the blood through the lungs.

On the other hand, it is lessened by low barometrical pressure; by high temperature of blood;

by superficial or slow respiration; and by rapid circulation through the lungs.

Under ordinary circumstances danger from these causes is easily averted with moderate care, for they do not often concur to produce the same effect; but if a patient, fatigued with struggling, takes a very deep breath just as fresh chloroform has been poured upon the towel, and then closes his glottis and makes another struggle—the barometer being high at the same time—it is evident that blood unduly charged with chloroform will gain access into the coronary arteries, and depress the cardiac ganglia. Death has occurred so rapidly under these circumstances, that it has been thought to be the result of shock from the operation.

Chloroform lessens, if it does not entirely prevent, the shock of an operation, but it is to be feared that if chloroform be given freely for this purpose, a dangerous amount of it will be administered.

If a severe operation is about to be performed, the chloroform should be given in the same gradual manner as in a slighter one, but continued to the point of fixing the pupils and producing stertorous breathing; and, when the chief shock is expected, two or three breaths of pure air should be admitted, so that, if the pulse fail, there may not be an excessive amount of chloroform-vapour in the lungs.

Compounds of Chloroform.—Under this head comes *Dichloride of Methylene*, which contains a variable quantity of chloroform. Its chemical characters and physiological effects are very similar to those of a mixture of chloroform, ether, and alcohol. It narcotizes quickly, but not safely; and, as the amount of chloroform in it is not always uniform, it is better to mix, in small quantities at a time, one part of alcohol, two of chloroform, and three of ether, and to keep the bottle so well corked that the ether is not likely to evaporate and leave chloroform in excess. The word ACE fixes the proportions in one's memory.

A mixture of one part of chloroform with four of ether is convenient for a brief operation, as this produces much less excitement than ether alone. On the whole the writer objects to keeping mixtures of this kind ready-made; and it is probable that the plan of giving at the outset sufficient chloroform to abolish consciousness, and subsequently administering ether, will be found safer than mixing them together in the liquid state.

Ethylene, &c. See APPENDIX.

AFTER-TREATMENT.—Quietude or conversation of an encouraging or soothing character is desirable during the half-minute of recovery from gas. The eyes should be covered, unless the view is tranquil as well as pleasant. If gas be given until there are intermissions in the breathing, or its administration continued for several minutes with a small allowance of air, there may be headache and even vomiting; still no other treatment than repose is needed.

After the inhalation of ether a taste will remain, varying with the strength of the vapour, and the duration of the administration. This may be got rid of by washing out the mouth, and gargling with warm fluids; while the vapour remaining about the patient and in the room may

be removed by heating the surface by means of hot bottles, and making a bright fire.

When the system has been long or profoundly under the influence of chloroform or ether, nausea and vomiting are likely to ensue. The writer has not found any remedies more efficient in relieving these symptoms than warmth, fresh air, and abstinence from food. Hot tea and coffee, taken from a feeder without raising the head, and afterwards beef tea and jelly, are sufficient for twenty-four hours, unless the patient wishes for something solid. The rule then should be to give as little as, or less than, is asked for. Ice has been recommended, and, if it does nothing else, it relieves thirst, and serves to postpone the necessity for giving solids which might prove hurtful.

TREATMENT OF DANGEROUS SYMPTOMS.—Anæsthetics in excess destroy life by stopping the action of the heart, or the respiration; generally both are affected. When laughing-gas is given to animals till the breathing has ceased, the heart continues to beat long afterwards, and artificial respiration rapidly restores them. Ether-vapour, given almost pure through a tracheal tube, will arrest the action of a dog's heart in sixteen seconds; but if administered as rapidly as possible with a cloth, without opening the trachea, the breathing fails before the heart, and the hemadynamometer shows adequate pressure in the vessels whilst the breath is gasping, and for several seconds after it has ceased.

With chloroform the hemadynamometer indicates diminished pressure directly the animal ceases to struggle, and the heart sometimes stops before the breathing. In case alarming symptoms should arise, the first effort should be directed to lessening the amount of the anæsthetic in the lungs, by pressing the trunk with both hands, and squeezing out as much air as possible without causing a shock. If, after this has been done two or three times, the air does not readily re-enter the chest, the obstruction is to be overcome either by lifting the chin or drawing out the tongue, and other artificial movements of the chest must be carried on. (See **ARTIFICIAL RESPIRATION**.) If pallor be noticed whilst breathing is going on, the recumbent posture and elevation of the feet are immediately required. (See **RESUSCITATION**.) Newton's plan of inverting the body has often been followed by recovery, but, considering the impediment to inspiration from the weight of the abdominal viscera, the writer is of opinion that the pelvis should never be many inches higher than the head. Nitrite of amyl—by reason of its effect in dilating the vessels of the skin—has been recommended, but without careful physiological inquiry, and upon very small clinical experience.

Electricity might be expected to prove the best agent to assist the action of a feeble heart. The writer's experimental observation has not been favourable to its employment; and certainly artificial respiration should not be delayed one moment in order to apply electricity.

Insufflation is not to be depended on. The condition would be rendered worse by distending the stomach, which cannot always be prevented by pressing the larynx against the spine.

Laryngotomy may be required in cases where in

spite of throwing the head backward, and removing the chin away from the sternum, air cannot be made to enter the chest.

Hot-water injections may be of use, but there can be no necessity for brandy whilst artificial breath^{ing} is being carried on. Afterwards, if swallowing is difficult, brandy may be added to the enema.

FriCTION of the limbs in the direction of the heart is unnecessary, provided the feet are slightly raised. Where there has been great loss of blood, the limbs should be bandaged firmly from the finger and toes upward, as in Eschsch's plan for saving the blood of a limb about to be amputated. In warm weather, or if the body is warm, a towel dipped in cold water may be flapped against the chest, but harm would result from cooling the body generally. Bottles of hot water and hot blankets should be applied as soon as the breathing is restored, and a brisk fire should be kept up, in order to favour the ventilation of the chamber. J. T. CLOWRY.

ANALGESIA (ἀ, priv., and ἄλγος, pain).—Absence of sensibility to painful impressions. See **SENSATION**, Disorders of.

ANAPHRODISIA (ἀ, priv., and Ἀφροδίτη, Venus).—Absence of sexual appetite. Sometimes used to express Impotence. See **SEXUAL FUNCTIONS**, Disorders of.

ANAPHRODISIACS.—**DEFINITION.**—Medicines which diminish the sexual passion.

ENUMERATION.—The agents employed as anaphrodisiacs are:—Ice, Cold Baths—local and general, Bromide of Potassium and Ammonium, Iodide of Potassium; Conium; Camphor; Digitalis, Purgatives, Nauseants, and Bleeding.

ACTION.—The erection which occurs in the genital organs during functional activity is due to dilatation of the arteries in their erectile tissues, and is regulated by a nervous centre situated in the lumbar portion of the spinal cord. From this centre vaso-inhibitory nerves pass to these arteries, and cause them to dilate whenever it is called into action. It may be excited either reflexly by stimulation of the sensory nerves of the genital organs and adjoining parts; or by psychical stimuli passing to it from the brain. Anaphrodisiacs may act by lessening the excitability of the nerves of the genital organs, as the continuous application of cold, and probably, also, bromide of potassium; by diminishing the excitability of the genital centres in the spinal cord and brain, as bromide and iodide of potassium and conium; or by influencing the circulation, as digitalis. There are also adjuvant measures, of a hygienic and moral character, which greatly assist and may even replace anaphrodisiac medicines, such as a meagre diet, especially of a vegetable nature, the avoidance of stimulants, and the pursuit of active mental and bodily exercise. Everything tending to stimulate the genital organs, or to increase the flow of blood to them or to the lumbar portion of the spinal cord, should be avoided, such as warm and heavy clothing, or pads about the hips or loins; and a hard mattress should be used in place of a feather-bed. Everything likely to arouse the passions, such as certain

novels, pictures, theatrical representations, &c. should also be shunned.

Usem.—Anaphrodisiacs are employed to lessen the sexual passions when these are abnormally excited in satyriasis, nymphomania, and allied conditions. As such excitement may sometimes depend on local irritation of the genitals, in consequence of prurigo of the external organs, excoriations of the os uteri, or balanitis; or on the presence of worms in the rectum or vagina, these sources of excitement should be looked for, and, if present, should be subjected to appropriate treatment.

T. LAUDER BRUNTON.

ANASARCA (ἀνά, through, and σάρξ, the flesh).—An effusion of serous fluid into the subcutaneous connective tissues, not limited to a particular locality, but becoming more or less diffused. See DROPSY.

ANCHYLOSIS (ἀγκύλος, crooked).—Marked stiffness or absolute fixation of a joint, which may be due to various morbid conditions of the structures entering into its formation. See JOINTS, Diseases of.

ANCHYLOSTOMA (ἀγκύλος, crooked, and στόμα, a mouth).—A genus of nematoid worms. See SCLEROSTOMA.

ANEURISM (ἀνεύρυσμα, I dilata).—DILATATION.—Aneurism is a local dilatation of an artery, leading to the formation of a tumour which contains blood, and the walls of which are composed either of the tissues of the vessel, or those which form its sheath or immediately surround it. Therefore every aneurism, properly so called, consists of two parts—a *sac* and its *contents*.

CLASSIFICATION.—Aneurisms are usually divided, according to the varying composition of the sac, into the following varieties.—

1. *True aneurism*, in which all the three coats of the artery form the sac or a portion of the sac. This variety is rare: at least it is so rarely possible to trace all the coats of the artery over any part of the sac beyond its orifice, that some pathologists deny the existence of this so called 'true' form of aneurism, and most admit its existence in the aorta only.

2. *Fulse aneurism*, in which the sac is formed by one only of the coats of the artery. This is almost always the external coat; but a sub-variety has been proved to exist as a consequence of wound of the outer part of the vessel, and is believed by some to take place spontaneously, in which the inner coat, or the inner and part of the middle coat, is dilated, pushed through the outer coat, and forms the sac. This is called *heretofore false aneurism*.

3. *Diffused or Consecutive aneurism*. Here the sac is formed of the sheath, cellular tissue, or other structures around the artery, which are matted together into the form of a membrane. The name 'diffused' is applied to this form of aneurism to express the fact that the blood is at first diffused amongst the tissues in consequence of the rupture or division, whether from injury or disease, of all the coats of the vessel, either in a part or the whole of its circumference; but it is not a good term, since, as soon as the aneurismal sac is formed, the blood is diffused no longer,

but, on the contrary, is encysted in the newly formed sac. So that the other term, 'consecutive,' seems a better one, expressing, as it does, the important fact that the formation of such aneurisms is always consecutive on a rupture, partial or entire, of the artery.

4. *Dissecting aneurism* is seen only within the trunk of the body, and always involving the aorta—although it may spread from the main artery down to its branches. In this form the internal and middle coats have given way, or cracked, and the blood has forced its way, usually into the substance of the middle coat, sometimes perhaps between the middle and outer coats, discharging the external portion of the vessel into a kind of aneurism.

This is the nomenclature still in common use; but as the first and second varieties are practically indistinguishable during life, and the first, though called the 'true' form of aneurism, is very rare, it would be better to include both under the common name 'true' aneurism, and apply the term 'false' to the third or 'consecutive' form.

5. Besides these, which are all forms of pure arterial aneurism, there are aneurisms in which the vein and artery are simultaneously involved, and which are therefore called *Arterio-venous*, which will be afterwards spoken of; and tumours having a certain analogy to aneurism, which are formed of dilated and tortuous arteries—*Cirsoid* and *Anastomotic* aneurisms.

Other classifications of great importance are, according to the cause of the disease, into *Spontaneous* and *Traumatic*; or, according to the shape of the tumour, into *Fusiform* and *Sacculated*. In *fusiform* aneurism there is a dilated tract of artery, often of considerable length, from either end of which springs the vessel of its natural calibre. *Sacculated* aneurism springs like a bud from one side of the vessel, and the artery is often buried for some distance in the wall of the aneurism, but there are many sacculated aneurisms which approach in shape to the fusiform, the vessel being dilated for some part of its extent, so that its two openings lie at different parts, and sometimes on different aspects of the sac.

ÆTIOLOGY AND PATHOLOGY.—The proximate cause of spontaneous aneurism appears to be usually a loss of the elasticity of the wall of the artery, whereby it loses its power of resilience after having been dilated by the force of the circulation. This loss of elasticity is commonly caused by atheroma or else by partial calcification of the wall of the artery. In the latter case the blood often forces its way through the entire arterial wall, and an aneurism of the consecutive variety forms,¹ or the external part of the artery is dissected off, and a dissecting aneurism results. Inflammatory softening of the artery, without the presence of any definite atheromatous deposit is looked upon by many writers of credit, such as Wilks and Moxon, as a common cause of aneurism. Such low inflammation may have its origin possibly in rheumatism—and, as a matter of fact aneurism is often preceded by acute rheumatism; more certainly in violent strain, or

¹ Sometimes, however, the bleeding will go on without the formation of any aneurismal sac, and lead to the loss of life or limb.

in mechanical violence. Anything else which weakens the arterial wall, such as the exposure of the vessel in an abscess, is looked on as a cause of aneurism. The yielding of a weakened arterial wall is doubtless accelerated by irregularities of the circulation. The influence of syphilis and of intemperance in causing aneurism is widely believed, though perhaps as yet neither fact is absolutely established: the latter, at any rate, is rendered very probable from the consideration that chronic alcoholism tends to impair the nutrition of all the tissues, including the arteries, and is accompanied by a constantly irritable condition of the circulation. That syphilis may cause a fibroid degeneration of the vessels must also be allowed to be at least possible, and that it does so is the opinion of many eminent pathologists. If so, the transition to aneurism is natural, if not inevitable. Another proved cause of aneurism is embolism, or the obstruction of a diseased artery by a fibrinous plug, which has been known to be followed by the dilatation of the artery immediately above the plug, just as in very rare cases the ligation of a healthy vessel has given rise to the formation of aneurism above the tied part.¹ Violence is a very frequent cause of aneurism, even in cases which are not technically denominated 'traumatic.' The latter term is generally restricted to cases in which the vessel is wounded by a cut, or is known to be ruptured, and the aneurism makes its appearance at once; and in these cases the aneurism is of the 'diffused' or 'consecutive' variety. But there are, no doubt, many cases in which the artery is partially torn, and the walls, being thus weakened, afterwards slowly yield at the injured spot. This fact is illustrated by the well known experiment of Richerand, designed to explain the frequency of popliteal aneurism. The experiment consists in hyperextension of the knee in the dead subject. If this be carried on forcibly till the ligaments are heard to crack, it will usually be found that the two inner coats of the popliteal artery are torn.

All these causes of aneurism act much more powerfully in later life than in childhood, and many are unknown in early years. Aneurism, therefore, is very rare in children. In cases where the arterial system is extensively affected with atheroma, a great number of aneurisms may be found in the same person, or another may form after the cure of the first. To such cases the term 'aneurismal diathesis' has been applied. This fact shows the great importance, in all cases of spontaneous aneurism, of examining the whole body to detect disease of the heart or any second aneurism which may exist.

Almost all aneurisms contain more or less *clot*, and much of this clot is usually of the laminated variety, consisting almost entirely of fibrine mixed with more or less of the blood-corpuscles. These laminated coagula adhere very firmly to the interior of the sac; they are arranged concentrically like the coats of an onion; and usually lose their colour in proportion to their remoteness from the blood which still circulates through the sac. Their deposition depends in a great

measure on the presence of rough projections from the wall or mouth of the sac, and on the shape of the aneurism. When the latter is purely cylindrical, much less coagulum, possibly none, will be found in it. When the tumour stands well away from the artery, so that the force of the circulation is much broken, the formation of coagula is greatly favoured. The deposition of such firm coagula must be looked on as the commencement of spontaneous cure, and at any rate defends the patient from the risks of rupture, or of renewed growth of the tumour at the parts which are so lined.

SYMPTOMS.—The symptoms of arterial aneurism are as follows:—There is a pulsating tumour, which is situated in the course of one of the arteries, and which cannot be drawn away from the vessel. The pulsation is equable and expansile, that is, it not only causes an up-and-down movement of the tumour, for such a movement may be communicated to any tumour by a large vessel lying in contact with it, but also expands the tumour laterally and in all other directions. The pulsation is in most cases accompanied by a *bruit* or blowing sound, heard on auscultation, which can be tolerably well imitated by the lips, and which is synchronous with the pulsation. Pressure on the artery above suspends both the pulsation and the bruit. Sometimes it may be noticed that the pulse below is retarded, that is, that it reaches the finger later than in the corresponding vessel on the other side. Besides these, which are the main signs of aneurism, there are others, which are of less constant occurrence or of subordinate importance. Thus, on compression of the artery above, the tumour will empty itself more or less completely, and the greater or less change of size under these conditions is a useful test of the proportion of fluid and solid in the sac. Sometimes pressure on the artery beyond the tumour may cause an increase in its size. The pulse below the tumour is often found to differ strikingly from that on the sound side. There are many and various symptoms due to the pressure of the aneurism on neighbouring veins, nerves, bones, and viscera—symptoms which are of subordinate importance in a diagnostic point of view in the case of external aneurism, but are often of the greatest value in thoracic and abdominal aneurisms. Thus dyspnoea and ringing cough from pressure on the trachea, spasm or paralysis of the vocal cords from pressure on the recurrent laryngeal nerve, pain in the back from pressure on the vertebrae, or neuralgic pains from pressure on the nerves at the root of the neck, are well-known symptoms of aortic aneurism; and, similarly, pain in the leg from pressure on the popliteal nerve, and oedema from compression of the vein are frequent symptoms of popliteal aneurism.

DIAGNOSIS.—The affections which are usually confounded with aneurism are tumours of various kinds lying upon arteries, abscesses, and cancerous tumours which have large vascular spaces in their interior, and therefore pulsate. The tumours which receive pulsation from arteries against which they lie are of various kinds; cysts and enlarged glands in the popliteal space, and enlargements of the thyroid body pressing

¹ For cases of this nature see *System of Surgery*, 2nd edit. vol. iii. p. 122

on the carotid or innominate artery, are the most familiar examples. The diagnosis is usually easy. They have commonly little or no bruit, though in some cases a dull thud is produced by their pressure on the artery; they have not the expansile pulsation of aneurism; they present no change in size or form when the circulation is stopped; and they can usually be drawn away from the artery sufficiently far to lose their pulsation. An abscess has been often mistaken for aneurism, but the mistake has generally proceeded from a neglect of auscultation.¹ There are a very few cases in which aneurisms have lost their pulsation in consequence of the rupture of the sac, and in which no bruit may be audible,² and such tumours can hardly be diagnosed from abscess except by an exploratory puncture, which under these circumstances is justifiable; these cases are, however, extremely rare. The disease most commonly mistaken for aneurism is pulsating cancer, and the resemblance has been sometimes so striking as to deceive the best surgeons, even after the fullest possible investigation of the case. These pulsating cancers almost always grow from the bones,³ and the neighbouring bone can generally be felt to be enlarged, which is rare in aneurism. They have not usually the well-marked bruit of an aneurism, nor is the bruit universal, the pulsation also is more indistinct, and not so expansile as in aneurism; and the growth of the tumour is more rapid.

COURSE AND TERMINATIONS.—Aneurism is generally a fatal disease if left to itself. The sac enlarges; parts of it give way, either by a process of inflammatory softening or by rupture; or it produces fatal pressure on the surrounding parts; or the whole tumour suppurates, and the patient dies of fever, of pyæmia, or of hæmorrhage. But to this general statement, independent altogether of what the effects of any special treatment may be, there are numerous exceptions. In some cases, and especially in the fusiform kind of aneurism, the tumour, after having attained a certain size, remains stationary, and this stationary condition is sometimes produced by a deposit of coagulum lining the sac, and leaving a canal through which the blood-stream passes, as through the normal artery. In these cases, however, the symptoms persist, but there are others in which a complete spontaneous cure is obtained, and this may happen in various ways.

Spontaneous Cure.—The first, and probably the most usual method of spontaneous cure is by the gradual diminution of the circulation through the tumour, and the gradual filling of the sac by successive layers of fibrinous coagulum. The second is by impaction of clot in the mouth of the aneurism, whereby in some cases possibly the sac of the aneurism is cut off from the blood-stream, and its contents brought to coagulate. In other cases, where more than one artery opens out of the sac, the impaction of clot in one of the distal arteries leads to consolidation of all that

part of the tumour through which the circulation used to pass into the obstructed vessel, and thus a practical cure is sometimes effected,⁴ i.e. the symptoms are cured and the disease arrested, though the whole sac is not obliterated. The third method of spontaneous cure is by inflammation of the tumour. There is usually accompanied by suppuration of the sac and evacuation of all the contents of the aneurism, the accompanying inflammation closing the mouths of the arteries which open out of it. If the arteries are not so closed, death from hæmorrhage will occur. It seems possible that inflammation of the sac and the cellular membrane around it may sometimes produce coagulation within the aneurism without any suppuration. A fourth way in which coagulation of an aneurism has been known to be caused is by retardation of the circulation or impaction of clot, caused by another aneurism above, and there is an old idea, which can hardly yet be said to be exploded, that an aneurismal sac may by its growth compress the artery, and so lead to its own coagulation. This, however, if it ever happens, is purely exceptional.

Rupture.—The rupture of an aneurism may take place either through the skin, in which case the hæmorrhage is usually, but not always, fatal at once;⁵ or into one of the cavities of the body, when death generally occurs immediately, if the rupture is into a serous cavity, and after one or two attacks of hæmorrhage if a mucous membrane has been involved; or lastly into the cellular tissue of a part. This event is marked by the cessation of the pulsation; the sudden swelling, accompanied with ecchymosis if the blood is effused subcutaneously; and the abrupt fall of temperature below the aneurism. A sensation of pain, or of 'something giving way,' is often experienced. Stethoscopic examination will probably detect a bruit.

TREATMENT.—a. MEDICAL.—The methods of treatment of aneurism are very numerous, and it would be impossible in a summary of this kind to discuss fully all the indications for each. In the first place, those aneurisms which are inaccessible to any local treatment, or in which local treatment would involve great danger, are treated *medically*, that is by regimen, diet, and medicine, by which it is hoped that gradual coagulation will be promoted in the contents of the tumour, and thus a complete or a partial cure will be brought about, as in the natural process above spoken of. The method of Valsalva, of which the main features were starving and excessive bleeding, and which therefore produced considerable and often dangerous irregularity of the heart's action, is now given up in favour of the opposite plan introduced by Bellingham and modified by Mr Jolliffe Tufnell,⁶ in which, by complete rest and restricted but nutritious diet, the absolute regularity of the heart's action is secured, and at a rate below that of health, both

¹ See a paper by the author in *St. George's Hospital Reports*, vol. vii. pp. 175 et seq.

² See a case under the care of the writer, reported in the same paper, p. 180.

³ In one case under the care of the writer the disease was unconnected with the bones, and affected the kidney only.—*Pathological Transactions*, vol. xxiv. p. 149.

⁴ See a case of innominate aneurism with remarks in the *Lancet*, June 16, 1872, p. 818.

⁵ Instances of successful ligation of the artery above after bleeding from ruptured aneurism are on record. See a case in the *Lancet*, 1861, vol. ii. p. 30. In which the femoral artery was successfully tied after the bursting of a femoral aneurism through the skin.

⁶ *The Successful Treatment of Internal Aneurism*. 2nd edit. 1875.

as to rapidity and force. Mr. Tufnell has given some interesting and conclusive examples of the complete cure of abdominal aneurisms thus accomplished, verified by dissection; and one, at least, in which an aneurism of the arch of the aorta was in all probability entirely consolidated, though this fact was not verified by dissection. At any rate the patient was permanently restored to health. In this method of treatment drugs are only employed when necessary (as narcotics, laxatives, and tonics often are) to ensure the regularity of the functions, to control irritability, or to support the general health. The drugs which have been recommended as producing a direct effect on aneurism by promoting the coagulation of blood in the sac, such as acetate of lead and iodide of potassium, do not, in the writer's opinion, produce any such effect, nor in fact any specific effect on the disease whatever. He has often seen a certain amount of improvement under the use of these drugs, but not, he thinks, more than the regimen and diet used at the same time would account for. Other drugs, as aconite and digitalis, are recommended in order to steady and reduce the heart's action, and the latter especially is sometimes a useful adjunct, if employed with caution, to the treatment by restricted diet and rest. The rest is *total*, the patient never leaving his bed, nor ever rising from it, or changing his position more than by occasionally turning on his side, the bowels are so regulated as to avoid both constipation and looseness; and the diet is restricted to about 10 oz of solid food, of which one half is meat or fish, and 8 oz. of fluid (comprising 2 or 3 oz. of light wine if necessary), per diem. The period may be extended indefinitely, so long as improvement continues; but in all cases the patient and his friends should be prepared for a confinement of not less than three months. See ABDOMINAL ANEURISM; and AORTA, Diseases of (*Aneurism*).

b. SURGICAL.—Most aneurisms which occupy an external position, and are therefore amenable to surgical treatment, are curable, when the degeneration of the vascular system is not too extensive, by mechanical means. Of these the chief and by far the most successful are either the *ligature of the artery*, whether in the sac, above it, or in some special cases below; or *compression*, applied either to the artery above the aneurism, or to the tumour itself, or simultaneously in both situations, and either by the pressure of an instrument, of the fingers, or of Eschmarch's bandage. But as these methods of treatment belong exclusively to the province of surgery, it is thought better in a work of this kind merely to name them, and to refer the reader to the standard works on surgery for their description.

The other methods of surgical treatment are far less successful than the above, and have the great drawback of being addressed exclusively to the contents of the sac, while in the treatment by the ligature and by compression the resilient power of the sac, and its consequent reaction on the blood which it contains, no doubt play a great part in the cure. The methods now to be mentioned, on the contrary, as far as they act on the sac at all, rather tend to contuse or to inflame it.

Galvanopuncture.—The first is galvanopuncture, in which a current of electricity of low tension, long continued, is passed through the blood in the sac, decomposing it, and causing its coagulation. Needles are plunged into the sac, and are then connected with the battery, and the action is continued until the reduction in the pulsation and the flattening of the tumour show that the blood has been partly coagulated. Authorities differ as to the details of the method. Some apply first the positive and then the negative pole to each needle, others the negative pole only, the positive being brought in contact with the neighbouring skin, while some on the contrary use the positive pole only. It will be found on experiment that a certain amount of coagulation takes place around both poles, the clot round the positive pole being smaller but firmer than that round the negative. The object of the operation is to fill the sac as much as possible with coagulum which shall gradually harden, and shall attract to itself fresh coagulum. The dangers of the proceeding are those of inflammation of the sac, or of the cellular tissue around it, of suppuration within the tumour; or of sloughing of the punctures and hemorrhage; and it must be allowed that the effects of galvanopuncture are very uncertain, both as to the amount and firmness of the coagulum produced. Still there is satisfactory evidence of benefit in many cases, and of a cure in a few. The danger of inflaming or cancrising the sac or the tissues around may be in some measure obviated by coating the needles with vaseline, as recommended by Dr John Duncan of Edinburgh. For a very clear exposition of the details of this method, as well as for statements regarding the success which has attended electrolysis hitherto, the reader is referred to a lecture by this gentleman, reported in the *British Medical Journal*, May 20, 1876. The writer thinks himself justified in adding that electrolysis should be restricted to cases of thoracic, subclavian, or abdominal aneurism, which cannot be cured by medical means, and in which rupture seems to be imminent, while the situation of the tumour forbids the application of pressure.

Coagulating Injections.—Another method of producing coagulation of the blood in the sac is by the use of coagulating injections. Other fluids have been employed, but the only one in general use now is the perchloride of iron. The circulation is to be suspended by pressure on the artery above, before the injection is made and for some time afterwards. The method is a very dangerous one for large aneurisms, on account of the risks of embolism, sloughing, and inflammation, but it may be used with success in small cirrhotic and anastomotic aneurisms, and also in varicose aneurism.

Introduction of foreign bodies.—Aneurisms have also been treated by the introduction of foreign bodies into the sac, with the view of producing coagulation of the blood upon the foreign substance, such as fine wire, carbonised catgut, and horsehair; but no case of cure has hitherto been reported.

Manipulation.—Finally, aneurisms may be treated by manipulation. The object of this treatment is either to detach a portion of coagu-

ism from the wall of the aneurism, which may be carried into the mouth of the sac or the distal artery, and so effect a cure as in our second mode of spontaneous cure, or at any rate so to disturb and break up the clot, that its detached laminae may form nuclei for further coagulation. With this view the aneurismal tumour is grasped between the two hands to squeeze all the fluid blood out of it, and one wall rubbed against the other till 'a friction of surfaces is felt within the flattened mass.' The proceeding is obviously a very dangerous and uncertain one, but some indubitable cures have been thus effected.

Arteriovenous Aneurisms.—A few words must be added with respect to the rarer forms of aneurism. Arteriovenous aneurisms are generally, but not always, traumatic, and are divided into two chief forms:—1. *Varicose aneurism*, in which there is a small aneurismal tumour communicating both with the artery and with a vein which is always varicose; and 2. *Aneurismal varix*, in which the opening between the two vessels is direct without any tumour interposed; the vein pulsates as well as being varicose, and the temperature of the limb and nutrition of the skin and hair are increased. In all forms of arteriovenous aneurism the artery after a time becomes thin and much dilated. The signs of arteriovenous differ from those of arterial aneurism mainly in this—that besides the intermittent blowing murmur caused by the arterial current, there is a continuous purring or rasping bruit due to the venous current, and that besides the intermittent pulsation there is a continuous thrill. Varicose aneurism may be cured by digital pressure applied directly to the venous orifice, and indirectly to the artery above at the same time; or the old operation may be performed, the clots being turned out of the sac and the artery tied above and below, the vein being of course laid open and secured either by ligature or pressure; or the artery may be tied above and below without opening the sac. Electropuncture and coagulating injections have also been used with success. Aneurismal varix does not usually require or admit of surgical treatment. If it does, the ligature of both parts of the artery is the only measure that can be adopted, on the failure of compression.

Circoid and Anastomotic Aneurisms.—*Circoid aneurism*, or *arterial varix*, is a tumour formed by the coils of a single dilated and elongated artery; * while *aneurism by anastomosis* is a tumour formed by the coils of numerous dilated and elongated arteries, with the dilated capillaries and veins which communicate with these arteries. It is often difficult to distinguish these two forms of arterial disease from each other. Aneurism by anastomosis frequently originates congenitally as one of the forms of nævus. The usual situation of these tumours is on the scalp. They have often a peculiar continuous buzzing or rushing murmur, which is propagated over the whole head, and much disturbs the patient's rest; while they are liable to ulcerate and to become the source of serious and even fatal hæmorrhage. Some cases of spontaneous cure

are on record. Very numerous methods of treatment have been employed, of which the writer can only mention those which are most generally useful. When feasible, the total removal of the tumour with the knife is certain to effect a radical cure, but this operation is often too dangerous to be attempted. The entire removal by ligature is still more rarely practicable. The galvanic cautery is often successful; the incandescent wire being drawn through the mass in various directions divides it into portions, and obliterates the vessels by producing cicatrices at the parts cauterised. Setons have also been used with success, when combined with the ligature of the trunk-artery; and the ligature of the artery alone has been said to be followed by success, but certainly is generally unsuccessful. Finally, coagulating injections and galvanopuncture have both effected a certain number of cures.

T. HOLMES.

ANGEIECTASIA (ἀγγειος, a vessel, and ἔκτασις, extension).—Extension or hypertrophy of the capillaries and minute vessels of the surfaces of the body, especially the skin; hence *angeiectasia capillaris*, a term applicable to several forms of vascular nævus.

ANGEIOLEUCITIS (ἀγγειος, a vessel, and λευκός, white).—Inflammation of lymphatic vessels. See LYMPHATIC SYSTEM, Diseases of.

ANGINA (ἄγχω, I seize by the throat, strangle, or choke).—SYNON.:—Fr. *angine*; Ger. *die Bräune*.

The term *angina* was originally applied by Latin writers on Physic, and is still much used on the Continent, to indicate a condition in which difficulty of breathing and of swallowing exist either together or separately, caused by disease situated between the mouth and the lungs, or between the mouth and the stomach. By a special affix to the original term, significative of the seat or the nature of the disease, several varieties of morbid states are known and described, for example:—*angina parotidea*, or mumps; *angina tonsillaris*, or quinsy; *angina laryngea*, or laryngitis; *angina pectoris*, or breast-pang; *angina maligna*, or malignant sore throat; *angina membranosa*, or croup.

These and numerous other diseases, differing essentially in their nature and pathological relations, and having nothing in common but certain difficulties in breathing or swallowing, are thus classed under the word *angina*. Such a classification is open to several objections, and has nothing to recommend it. With the exception, therefore, of *angina pectoris*, which has a special and familiar signification, the various diseases occasionally recognised by the term *angina* will be found described under the names by which they are generally known in this country. See also CYANACHE.

R. QUAIN, M.D.

ANGINA PECTORIS.—SYNON.: Syncope Anginosa; Angor Pectoris, Suffocative Breast-pang. Fr. *Angine de poitrine*; Ger. *Brustbraune*.

DEFINITION.—An affection of the chest, characterised by severe pain, faintness, and anxiety, occurring in paroxysms: connected with disorders of the pneumogastric and sympathetic nerves and

* Mr W. Ferguson, *Med. Chir. Trans.* xl. 8.

* See the figure on p. 534, vol. III. of the *System of Surgery*, 2nd edition.

their branches; and frequently associated with organic disease of the heart.

DESCRIPTION.—An attack of angina pectoris commences suddenly with pain in the region of the heart, generally on a level with the lower end of the sternum. The pain is severe, and of a grasping, crushing, or stabbing character; it extends sometimes across the chest, but more frequently backwards to the scapula, and upwards to the left shoulder and arm. The pain is accompanied by a distressing sense of sinking, of faintness, or of impending death. The action of the heart is generally irregular. The pulse at the wrist corresponds; but in some well-marked cases it is regular, tense, and resisting. A fear of aggravating the pain prevents the patient from breathing, though the respiratory function may not be really interfered with. The expression is anxious, the face is pallid, and the lips are more or less livid. The whole surface of the body is pale, cold, and covered with a clammy sweat. Flatulence is often present; urine in some cases is passed at short intervals, and generally in abundance. The sense of faintness causes the patient to seek support, and he rests on any object by which this may be obtained. The attack having lasted for a variable time—from a few minutes to one or two hours—comes to an end, either by a sudden cessation of the more urgent symptoms, or by their gradual disappearance. The pallor and coldness of the surface are replaced by a uniform glow—the face may even flush, the pulse becoming soft and full, and there is a general feeling of relief; a sense of numbness or tingling along the course of the nerves derived from the brachial and cervical plexuses of the affected side occasionally remains. An attack of angina pectoris frequently comes on during sleep; but it may be induced by emotion or by physical exertion, especially by walking up an ascent, or by exposure to cold air or wind. An attack of this kind may occur but once and end fatally; or it may recur after an interval of hours, days, or weeks, and be thus continued; or there may be an interval even of years. These and other modifications of the disease will be again referred to.

PATHOLOGY.—The nature of the aggregate of the symptoms or phenomena comprised under the name *angina pectoris*, cannot be understood without a clear apprehension of the relations of the nerve-elements of the organs and regions that seem to be involved in the affection. It will be well briefly to summarise them.

The nerves chiefly involved are the pneumogastric and the sympathetic, and their branches, which nerves, it should here be stated, are connected with each other at their origin in the medulla oblongata, in their course, and in their distribution to the ganglia and structures of the heart. They also communicate with certain of the cerebral nerves, and with the cervical and brachial plexuses, which supply part of the head and neck, the arms, the diaphragm, and the chest-wall. Their connections with the heart are very extensive. This organ is supplied by the cardiac ganglia and the branches derived from them, which are in relation with, and, in fact, constitute part of the cardiac plexus formed by the interlacement of branches from

the pneumogastric and the sympathetic nerves. The pneumogastric supplies the superior cardiac nerve and apparently the inferior cardiac nerve (which, however, is derived from the spinal accessory, and is merely distributed with the pneumogastric); the sympathetic contributes several branches through the cervical ganglia. Branches of both pneumogastric and sympathetic nerves are distributed to the respiratory passages, the lungs, stomach, intestines, liver, and other abdominal viscera.

The connection of the pneumogastric and sympathetic nerves in the medulla, to which allusion has been made, occurs at the cardiac and vaso-motor centres; and consequently these nerves, and the heart (which they supply) are thus brought into relation with the vaso-motor nerves throughout the body, and with all the systemic blood-vessels; they are also in relation with the other important centres in the neighbourhood; and with the cerebrum itself, more especially that part of it associated with the emotions.

Such being the distribution and the relation of the nerves connected with the heart and surrounding parts, we learn, in reference to their functions, that the movements of the heart are maintained by its ganglia, but that these movements may be accelerated by the action of the sympathetic, whilst they are controlled and may be even arrested by that of the inferior cardiac branch from the pneumogastric.

The superior cardiac branch of the pneumogastric has to do with the specific function of conveying impressions contripetally from the heart to the medulla, whence these impressions may be reflected through the inferior cardiac nerve to the heart, controlling for a time its movements; and also reflected through the vaso-motor centre and vaso-motor nerves, to the general circulation. By means of this latter functional relation, relaxation of the arteries, especially those of the abdomen through the splanchnic nerves is accomplished, and the heart is relieved of pressure.

With regard to other functions of the cardiac nerves, it is believed that such common sensibility as the heart possesses is more especially connected with the superior cardiac branch of the pneumogastric. Numerous communications exist between this nerve and the ordinary spinal nerves; and it must also be remembered in reference to the sites of pain in angina, that nerves may be rendered sensitive by disease which are not sensitive in health.

Lastly, it is to be noted that the pneumogastric and sympathetic nerves, as well as the heart and blood-vessels, whose functions they regulate, possess the extensive connections above mentioned with the abdominal and thoracic viscera, and thus they not only influence but are influenced by the conditions of the lungs, liver, stomach, kidneys, and other organs.

Keeping in mind this distribution of nerves and their functions, we can recognise how the movements of the heart may be affected, whether in the direction of acceleration, retardation, or even arrest. We can further understand how painful impressions originating in the cardiac nerves may be propagated so as to be referred

to the associated sensory nerves and their branches; and how relations may be established with the vaso-motor system and the circulation generally. Thus the vessels throughout the body may be acted upon, producing coldness and pallor of surface from the abnormal filling of the abdominal at the expense of the superficial vessels, a condition which seems to be the cause of the diminished arterial tension noticed in these cases. We can also comprehend how morbid impressions made either on these nerves, in their distribution to the abdominal viscera or the heart, or on the peripheral distribution of the vaso-motor nerves at the surface of the body, may, passing centripetally, admit of reflex impressions and reflex actions, which in some cases may be provocative of the symptoms of this disease: also how direct impressions made on the nerves themselves in their course, or at the vaso-motor centre, or through the cerebral emotive centres, may each give rise to the phenomena which represent the symptoms constituting angina pectoris.

Pathology of Uncomplicated Angina Pectoris—That this disease is dependent on an affection of nerves may be held to be demonstrated by the paroxysmal character of the attack, by its sudden access and sudden departure, by the nature of the causes that promote it, whether they be mental emotion or direct or reflected irritation, by the course and character of the pain, and by the fact that in severe—even fatal—instances of angina, there is often an absence of any tangible or evident organic local disease.

The morbid state affecting the nerves may be situated in the medulla; or it may be in the course of these nerves, or in their branches, or in the cardiac ganglia themselves. It may be the result of congestion or inflammation of the nerve, such as occurs in the lithic acid or gouty diathesis; or of other textural changes, such as connective-tissue growth, involving the nerve-fibres and ganglia. It may be produced by emotions acting centrifugally; or by irritation acting centripetally, reflected, as we have just said, from impressions made on the peripheral extremities of nerves. Thus acidity of the stomach distended by flatus, the result of indigestion, often gives rise to symptoms which very closely resemble, if they do not constitute, an attack of angina. The like effect has been produced by irritation reflected from the fifth nerve, as, for example, in pivoting teeth; by such irritation of the surface of the skin as results from severe herpes; by cold, or by exposure to wind. But the most frequent source of the symptoms of angina caused by reflex action is to be found in those organic affections of the heart which will be described in the next section.

Whatever the nature of the irritation or of the exciting cause, the symptoms will, in some measure, bear a relation to the nerves affected. Thus, if the sensory branches connected with the spinal nerves suffer, we shall probably have pain more severe and more diffused: whereas if the branches more immediately supplying the heart are affected, we shall have the action of that organ more or less disturbed, accelerated or depressed. And so with the branches of other

nerves, more especially of those connected with the vaso-motor system, or with the lungs and abdominal viscera, modifications of symptoms are produced which it is needless to describe at this point in detail.

Pathology of Angina Pectoris complicated with Organic Disease of the Heart and Vessels.—

The striking character of the symptoms of angina pectoris has led pathologists to connect the heart with the disease, and to investigate its condition accordingly. Such researches have established the fact already mentioned, that angina may exist without any discoverable disease in the heart or its appendages. On the other hand, in the great majority of cases various forms of structural disease of the heart and aorta have been observed; for example atheromatous or calcareous degeneration in the coronary arteries, in the valves, or in the aorta; dilatation of the cavities of the heart, or of the aorta, accumulation of fat in the cardiac walls, and lastly, and probably the most important change of all, fatty degeneration of the muscular tissue. A knowledge of this lesion is of comparatively recent date, it is constantly associated with the calcareous and atheromatous diseases described above, and which alone attracted the notice of older observers. Nay more, this lesion of the walls of the heart is in itself a frequent and sufficient cause of one of the most prominent symptoms of angina pectoris—faintness. This condition has been elsewhere described by the present writer (*Medical and Chirurgical Society's Transactions*, vol. xxxiii.) under the name of *Syncope Lethalis* or fatal-faintness—a designation analogous to that given by Parry to angina pectoris, which he called *Syncope Anginalis*.

Ætiology—When treating of the pathology of angina pectoris we have already discussed the conditions under which it occurs. We have endeavoured to show that the disease consists in a lesion of certain nerves, associated with various morbid conditions. In seeking to indicate the *pre-disposing causes* of these conditions, we have to point out (1) the existence of a peculiar state of the nervous system, which may be described as an undue susceptibility to impressions. What that state is we know not. It would seem to be often hereditary, and to be found in those temperaments in which there is a high development of the nervous element, associated with certain habits of life, such as sedentary employments, high living, and so on. Thus it is that this disease has been the cause of the death of many men who, by their intellectual pursuits, have left their mark on history. It is merely necessary to mention, as instances, Lord Clarendon, John Hunter, Dr. Arnold. (2) The influence of age is conspicuous; the disease is rare before puberty, and the writer's researches show that quite eighty per cent. of cases occur after forty years of age. (3) Sex also displays a marked influence on the disease, it is comparatively rare amongst women, a statement by the late Sir John Forbes showing that out of 49 fatal cases, only 2 occurred in females; and 4 out of 15 non-fatal cases—facts entirely corresponding with the writer's experience. (4) The peculiar diathesis which gives rise to neuralgia of various parts, and that is

which lithic acid predominates in the system, would seem to be in many cases an efficient cause of the symptoms of angina.

The *exciting causes* of angina pectoris are (1) Those that affect the nerve textures themselves. (2) The condition to which we have referred, in which organic disease of the heart exists. (3) Mental emotion, especially anger or nervous shock. (4) Irritation propagated centripetally from the surface, as by the branches of the fifth nerve; through the brachial plexus, through the sympathetic and pneumogastric nerves distributed to the abdominal viscera. (5) Cold applied to the surface, and especially cold winds. (6) Physical exertion, or any other agency by which the circulation is quickened. (7) Depressing agents, such as excessive tobacco smoking, malaria, &c.

ANATOMICAL CHARACTER.—Beyond the conditions indicated under the head of Pathology, there is little to be said on the morbid anatomy of angina pectoris. These several conditions, and the symptoms of angina as above described have been found to exist independently of each other. There must therefore be something in the state of the nervous tissues that acts as the predisposing or exciting cause of this aggregate of phenomena. Inflammatory changes and tumours, involving the vagus or the cardiac plexus, have been observed and described. With reference to the state of the heart itself, its cavities have been found dilated and containing blood, or contracted and empty, and theories have been founded thereupon, as to whether death occurred by spasm or by paralysis. It is more than probable that either one or the other of these conditions may occur in angina, and lead to fatal results, according to the particular nerves controlling the functions of the heart which are affected. See PNEUMOGASTRIC NERVE, Disease of.

CLINICAL VARIETIES.—All the phenomena of an anginal seizure as above described may be more or less modified. The attack, though generally induced by exertion, may come on when the patient is at rest, and not unfrequently it sets in during sleep. The pain may be comparatively slight, and as such may recur occasionally, it may be, for months or years. On the other hand, it may be so severe as to mark a first, a single, and a fatal attack. In its character the pain may be stabbing or burning, but it is more frequently described as grasping, crushing, or oppressive. It may be limited almost to the region of the heart, or the lower part of the sternum; it may extend all over the chest to both arms, or spread to the side of the head and neck and down one or both legs, and it may in some cases apparently involve the diaphragm. The action of the heart may be slow, weak, and fluttering; or excited and bounding—constituting palpitation; and it may be regular or irregular. The pulse corresponds with the heart's action, in the early stage of a genuine attack it sometimes yields a sphygmographic tracing indicative of extremely high tension. The breathing is sometimes distressing; and although the patient can take a deep breath when asked to do so, he generally avoids this through fear of aggravating the pain. There may be laryngeal spasm. The mental functions are generally undisturbed; yet there

is sometimes slight wandering as the attack passes off, and unconsciousness is said to be occasionally observed. The sense of danger of impending death is a characteristic symptom of angina, and one not often absent; whilst a sensation of gasping or choking with difficulty in swallowing is occasionally present. The position of the patient varies; sometimes he sits, sometimes he stands, resting his arms on any convenient object to obtain support; sometimes he sits and stoops, or leans forward. As a rule the attack passes off as abruptly as it commenced, leaving the sufferer free from discomfort, in other cases its disappearance is more slow. The varieties in the symptoms of angina pectoris are thus seen to be remarkably numerous, constituting a form of disease which may be comparatively mild and of long duration, or one of intense suffering, hastening to a fatal termination.¹

COMPLICATIONS.—Amongst the diseases with which angina pectoris may be said to be associated, rather than complicated, are disorders of the liver and digestive functions, gout, albuminuria, diabetes, and certain diseases of the nervous system. Indeed, so marked is the latter connection, that Troussseau dwelt on the relation between epilepsy and angina—a relation which seems to depend on the susceptibility to nervous maladies which some individuals present, rather than on any special identity between these two diseases. More than one striking example of the connexion has fallen under the writer's notice; he might mention an instance recently met with in which this susceptibility was such, that an oppressive meal of indigestible food brought on a first and distressing anginal attack, followed by others. In this case brain disease with epilepsy was subsequently developed on the disappearance of the angina.

PROGRESS, DURATION, AND TERMINATIONS.—The progress and duration of this disease will depend wholly upon the nature of its cause. Cases have been recorded in which the first attack proved fatal. The writer has seen several; in three of these cases a *post-mortem* examination revealed the fact that there was slight partial hemorrhage into the walls of the heart, which had been the seat of fatty degeneration, connected with calcification of the coronary arteries. The symptoms in these cases perfectly resembled those of the most severe examples of angina pectoris. It is highly probable, therefore, that

¹ A case has recently come under the writer's notice in which a gentleman accustomed to pass lithic acid, and who for several years has had pains over the right side of the chest as low as the hypochondrium, was seized at night with a severe aggravation of these pains, coldness of the surface, irregular action of the heart, depression, and other symptoms, which, had the attack commenced on the left side of the chest, would have been really called angina pectoris. Similar attacks recurred at intervals for some weeks; they were easily brought on even by walking on a level surface for a few hundred yards. The most careful examination failed to elicit any evidence of organic disease in the organs of circulation or respiration. The patient was recommended to try a course of Homburg waters, and a short residence in Switzerland; from which he returned greatly improved, and almost free from pain. It should be mentioned that an interesting case has recently been recorded by Dr. Marston in which disease of the right side of the heart was accompanied by symptoms of angina affecting the corresponding side of the chest and arm.

some of the cases proving fatal in a first attack of the disease are rather examples of partial rupture of the heart than of what is usually called angina. On the other hand, cases of the disease may continue with interruptions for years, the difference being entirely due to the nature of the cause on which the disease depends. Thus in many instances individuals present all the symptoms of marked angina, accompanied by most of its distressing phenomena, and by the anxieties and fears that they beget; yet these cases, having more a neurotic or gouty origin, yield to treatment, the sufferers being restored to health, and continuing for years to enjoy comparative comfort. On the contrary, in the cases in which angina is connected with organic disease of the heart or of the nerves intimately connected with cardiac action, the symptoms progress in frequency and severity; and the attacks tend, with more or less certainty, to a fatal termination—it may be within a few days or weeks, or it may be, in milder cases, not for years.

DIAGNOSIS.—A typical case of angina pectoris, such as has been described at the commencement of this article, can hardly be mistaken. But when the several symptoms constituting an attack are variously modified, some being lessened in severity and others exaggerated; or when these symptoms depend on, so to speak, remote and removable causes; it is often difficult to say how far the disease is what may be regarded as a passing neuralgia, or an attack of what is commonly recognised as angina pectoris. So also it may be difficult to say, in cases of angina, whether the seizure is dependent on organic lesions which admit of no improvement, or on some condition that is amenable to treatment. It is, therefore, with this, as with most other affections, more difficult to determine the cause on which the symptoms depend, than to recognise the presence of the disease itself. With reference to the diagnosis of the organic diseases of the heart above alluded to, it is unnecessary to repeat here what will be found described under other heads. It remains but to say that in every case the closest scrutiny must be made into the condition of the heart and great blood-vessels, with a view to determine the presence or absence of organic disease. The investigation must further extend to the other viscera, such as the liver, stomach, and the digestive organs generally, as well as to the several other sources from which symptoms of angina may be excited by reflected irritation. Certain symptoms resulting from the presence of other diseases should not be confounded with angina—such, for example, as the pain and dyspnoea caused by pressure of aneurisms or of tumours within the chest; by rheumatic or gouty neuralgia of the chest-walls; by pleurodynia, or acute pleurisy; or by indigestion. Each and all of these conditions must be considered by way of exclusion in determining the nature and origin of the disease.

PROGNOSIS.—In anticipating the future of an attack of angina pectoris, one must be guided chiefly by a knowledge of its cause; in some respects also by its severity; and by the previous history of the case. Thus, if we can ascertain that the attack has been brought

on by some clearly established and removable cause, a favourable prognosis may be fairly entertained. On the other hand, if the history of the case tells that there have been several previous attacks, increasing in severity and connected with heart-disease, one can scarcely avoid being led to the conclusion that the disease will tend, with more or less rapidity, to a fatal termination. Between these two classes of cases exist a large majority of the examples of the disease in which the symptoms of angina, of greater or less severity, depend on neurosis, on gouty diathesis or on other sources of nerve disorder, amenable to treatment; and in which, therefore, a favourable prognosis may to some extent be given. But in all cases great caution should be exercised, for many instances occur in which, from slight and obscure beginnings, severe and even fatal examples of the disease have been developed.

TREATMENT.—The treatment of angina pectoris must first have reference to relief of the attack itself, and, secondly, during the interval to the removal of the causes on which the attacks may depend.

During the attack, it is necessary first, if possible, to inspire confidence, and remove apprehension. The patient should be allowed to retain the position in which he feels most comfort. Secondly, if the exciting cause is one that can be removed, this should be done; for example, if the stomach be full of undigested food, an emetic of mustard might be given with advantage; or if flatulence be present, peppermint, ether, and other anti-spasmodics will be useful. If cold have produced the seizure, the feet and hands should be immersed in hot water, hot bottles applied to the surface of the body, and poultices of linseed or mustard, or embrocations of chloroform or laudanum, should be placed on the chest. The administration of chloroform internally had better be avoided. The nitrite of amyl, as recommended by Dr. Lauder Brunton, has been found one of the most efficient remedies employed hitherto. Five or six minims of this drug (preserved in a glass capsule) should be inhaled from a handkerchief, and, if necessary, the inhalation may be repeated. Nitro-glycerine is useful ($\frac{1}{100}$ of a minim dose), and hypodermic injection of morphia may be tried with advantage. In cases where debility and exhaustion exist, the ordinary stimulants will be required; and various antispasmodics, such as ether, ammonia, &c., may be given with more or less benefit.

During the intervals—It is of course desirable to avoid all causes likely to bring on an attack of angina, such as mental excitement, bodily exertion, exposure to cold, and the use of indigestible food or heavy meals. The leading principle in treatment should, however, be to endeavour to determine and to remove, if possible, the cause of the disease. Whether it depend on organic disease of the heart, whether on simple neuralgia, whether on gout or dyspepsia, whether on debility, or on fulness of habit—to each of such conditions must appropriate treatment be directed. A variety of specific remedies have been recommended: such as arsenic, phosphorus, steel, zinc, and the different

anti-spasmodics. Galvanism, in the form of the continuous current from thirty cells, has proved successful in some uncomplicated cases, the positive pole being placed on the sternum, and the negative on the lower cervical vertebra. Excellent, however, as each of the remedies named may be under special and suitable circumstances, the result of treatment must entirely depend on the cause of the disease, and how far it is within reach of remedy. Some cases of apparently severe angina will be found to yield to treatment; whilst, as might be expected from the nature of the disease, others unhappily proceed to a fatal termination in spite of every effort directed to their relief.

R. QUAIN, M.D.

ANIDROSIS (ἀ, priv., and ἰδρῶν, sweat).

—Absence or want of perspiration. See PERSPIRATION, Disorders of.

ANILINE POISON.—The aniline dyes, which are a modern discovery, present the most brilliant hues of yellow, blue, and red; as such they have been used for dyeing stockings, gloves, &c. These articles when worn are apt to produce an intense form of inflammation and vesication of the skin, which is rebellious against treatment, and liable to relapse for many months after the original attack has subsided. See DERMATITIS.

ANIMAL POISONS. See POISONS.

ANODYNES (ἀ, priv., and ὄδυν, pain).

—DEFINITION.—Medicines which relieve pain by lessening the excitability of nerves or of nerve-centres.

ENUMERATION.—Anodyne medicines include Opium and its alkaloids—Morphia and Codein; Bromide of Potassium; Cannabis Indica; Belladonna and its alkaloid—Atropia; Hyoscyamus and Hyoscyamin; Stramonium; Aconite and Aconitia; Veratrum and Veratria; Conium and Conia; Lupulus and Lupulin; Gelsemium; Chloroform, Ether, and their allies—Chloral-hydrate; Butyl-chloral-hydrate; and Camphor.

ACTION.—Pain is due to a violent stimulation of a sensory nerve being conveyed to some of the encephalic nerve-centres (probably the cerebral hemispheres), and perceived there. The impression produced on all sensory nerves, except the cephalic nerves, is conveyed for a part of its course to the head along the spinal cord. The primary impression which is felt as pain, is usually made upon the peripheral ends of the sensory nerves; but it may also be made upon their trunks, upon the spinal cord, or possibly upon the encephalic centres directly, without any affection of the nerves themselves, as, for example, in hysteria. Pain may therefore be relieved, while the source of irritation still remains, by lessening the excitability of the ends of the sensory nerves which receive the painful impression; of their trunks; of the spinal cord along which the impression travels; or of the encephalic centre in which it is perceived. Opium acts by lessening the excitability of the sensory nerves, the spinal cord, and the encephalic ganglia; bromide of potassium is also believed to act on all three, although to a much less degree than opium; belladonna and atropia affect the sensory nerves, as probably does hyoscyamus;

stramonium, aconite and aconitia, veratria, chloral and butyl-chloral, lupulus and lupulin, and gelsemium probably act on the encephalic centres.

Uses.—As opium and morphia act upon all the nervous structures concerned in the production of pain, they may be used to relieve pain whatever its cause. Cannabis indica and bromide of potassium may be employed under the same circumstances as opium, but they have very much less power. Chloral seems to relieve pain only by inducing sleep, and does not produce an anæsthetic effect unless it is given in dangerous doses. Butyl-chloral also induces sleep, but seems to have a special sedative action on the fifth nerve; so likewise has gelsemium—and hence both these agents are used in the treatment of facial neuralgia. As the action of belladonna is exerted chiefly on the peripheral ends of the sensory nerves, this remedy is usually applied directly to the painful part in the form of plaster, liniment, or ointment. Aconite, veratria, and opium are also used as local applications in several forms, for the relief of pain. The various anodynes may be administered not only by the mouth, but by other channels, such as by inhalation, by enema or suppository, by hypodermic injection, or by endermic application.

Several therapeutic measures are employed as Anodynes, such as the application of Dry or Moist Heat; Cold; Electricity; various forms of Counter-Irritation; Acupuncture; or the Abstraction of Blood.

T. LAUDER BRUNTON.

ANOREXIA (ἀ, priv., and ὄρεξις, appetite).—Want or deficiency of appetite, not accompanied with disgust for food. See APPETITE, Morbid conditions of.

ANOSMIA (ἀ, priv., and ὀσμή, smell).—Loss of the sense of smell. See SMELL, Disorders of.

ANTACIDS—DEFINITION.—Medicines used to counteract acidity of the secretions.

ENUMERATION.—The antacids include Potash, Soda, Lithia, Ammonia, Lime, Magnesia, and their carbonates; as well as the salts which the alkalis form with vegetable acids, such as Acetates, Citrates, and Tartarates.

ACTION.—Antacids are divided into (1) those which act *directly*, lessening acidity in the stomach; and (2) those which act *remotely*, diminishing acidity of the urine. The alkalis and alkaline earths and their carbonates, with the exception of ammonia, have both a direct and a remote influence; for when swallowed they act on the stomach, and being absorbed from the intestinal canal, they are excreted by the kidneys, thus lessening the acidity of the urine. Ammonia and its carbonate are direct but not remote antacids; for, although they neutralize acidity in the stomach, they are partly excreted in the form of urea, and do not diminish the acidity of the urine. The acetates, citrates, and tartarates or the alkalis and alkaline earths, on the other hand, have no antacid effect in the stomach, but undergo combustion in the blood, being converted into carbonates, in which form they are excreted in the urine, and diminish its acidity.

Uses.—Excessive acidity of the contents of the stomach gives rise to acid eructations and

heartburns. It may sometimes depend on the secretion of a too acid juice by the stomach, but probably is generally caused by the formation of acid from the decomposition of food when the process of digestion is slow and imperfect. Antacids are given after meals to lessen acidity in the stomach, and afford immediate relief to its attendant symptoms. They may prove even more efficacious by preventing acidity when given before meals (*see* ALKALIS). If the action of the bowels be regular, soda is preferable; but lime should be used if they are relaxed, and magnesia if there is a tendency to constipation. Remote antacids are given to lessen the acidity and irritating qualities of the urine in cystitis and gonorrhoea, and to prevent the deposition of uric acid gravel or calculus in gouty persons. For this purpose potash and lithia are preferable, as their urates are more soluble than those of the other bases.

T. LAUDER BRUNTON.

ANTAGONISM.—This term is employed to express the fact that the physiological action of certain substances may be affected, even to the extent of neutralisation, by the presence in the body, at the same time, of other substances having an action of an opposite character. It is important to distinguish between *antidotal action* and *physiological antagonism*. By an *antidote* is meant a substance which so affects the chemical or physical characters of a poison, as to prevent its having any injurious action on living animal tissues. Thus acids and alkalis neutralise each other, so as to form innocuous salts; tannin may render tartar-emetic and many vegetable alkaloids insoluble; and the hydrated sesquioxide of iron may be used to precipitate arsenious acid. In these cases, the action is limited chiefly to the alimentary canal, and the object of administering the antidote is to form insoluble salts, or compounds which will be physiologically inert. But the *physiological antagonism* of certain substances is presumed to take place in the blood or in the tissues. When such a substance as strychnia, for example, is introduced into the alimentary canal, it is quickly absorbed, and carried by the blood throughout the body. It does not, so far as observation has discovered, influence all the tissues; but it so affects the spinal cord, and possibly the brain, as to give rise to severe tetanic convulsions, chiefly of a reflex character. This effect is, no doubt, due either to some interference in the nutritional changes between the blood and the tissues composing the nerve-centres; or to some specific action of the poison on the nerve-centres themselves (*see* AFFINITY). These changes, which are termed physiological, and on which the normal action of the nerve-centres depends, are probably of a molecular or chemical nature; and it is possible to conceive that they may be modified in different ways by different substances. Thus has arisen the idea of physiological antagonism; and experiment has shown that, within certain limits, which will no doubt vary in each case, such an antagonism is possible. Antagonism may be either local, affecting one organ, as is seen in the opposite effects upon the pupil of opium or morphia upon the

one hand, and stramonium, hyoscyamus, or belladonna upon the other; or it may extend apparently to more important organs or groups of organs, as in the case of the antagonism between strychnia and the hydrate of chloral. The most important investigations upon the subject of physiological antagonism are the following:—

(1) *Physostigma* and *Atropia*, by Professor Fraser—an inquiry which showed that the fatal effect of three and a half times the minimum fatal dose of physostigma may be prevented by atropia. (2) *Atropia* and *Prussic Acid*, a research by Preyer of Jena—of a more doubtful character as regards the point to be proved, but still sufficient to show that, within certain limits not yet indicated, it is possible to prevent the fatal action of prussic acid by atropia. (3) *Atropia* and *Muscarrin* (the active principle of *Agave muscarum*):—which were found by Schmiedeberg and Koppe to have entirely antagonistic actions on the ganglia of the heart—muscarin exciting the intra-cardiac inhibitory centres, and stopping the heart in diastole, while atropia has the contrary effect. (4) *Chloral* and *Strychnia*,—an antagonism first pointed out by Oscar Liebreich, who showed that minute doses of strychnia might so rouse an animal from the effects of an overdose of chloral as even to save its life. And (5) *Strychnia* and *Chloral*—with respect to which Hughes Bennett demonstrated the converse of the last-mentioned observation, namely, that in the rabbit a fatal dose of strychnia might be so antagonised by a dose of chloral as to save life.

CONCLUSIONS.—It has unfortunately to be admitted that the practical results of the preceding researches have not been very encouraging. In all of these investigations it was quite apparent that the limits of physiological antagonism were very narrow. Three elements affect the chances of success in the way of saving life:—(1) the age and strength of the animal, (2) the amount of the doses of the two active substances—so that if either the one or the other active substance be given slightly in excess, death will probably take place, and (3) the time between the administration of the two active substances. If the stronger be introduced first, and be allowed to manifest distinctly its physiological action, it is almost impossible to counteract this by that of another substance; but if the two substances be introduced simultaneously, or if the supposed antagonist to the more active substance be introduced first, the chances of success are much greater. It is apparent, therefore, that the facts relating to physiological antagonism at present known in science do not hold out much hope of good results from their application in practice; but still the physiological facts are so definite as to indicate a precise mode of treatment. For example, no one acquainted with the investigations mentioned above would hesitate in attempting to relieve the tetanic spasms of a case of poisoning by strychnia by repeated doses of hydrate of chloral, or by the administration of chloroform. A practical result of such researches is that the principle of physiological antagonism may serve as a guide to the application of re-

medies in disease. Thus excessive secretion, say from mucous membranes or from salivary glands, may be modified or arrested by the use of sulphate of atropia, a striking experimental demonstration of which may be seen in the antagonism between bromal hydrate and sulphate of atropia in the rabbit.

JOHN G. MCKENDRICK.

ANTEFLEXION.—A bending forwards of any organ. The term is specially used in relation to the uterus, when this organ is bent forwards at the line of junction of its body and cervix. *See* WOMEN, Diseases of.

ANTEVERSION.—A displacement forwards of any organ. The term is particularly applied to a change of position of the uterus, in which this organ is bodily displaced in the pelvic cavity, so that the fundus is directed against the bladder, and the cervix towards the sacrum. *See* WOMEN, Diseases of.

ANTHELMINTICS (ἀντὶ, against, and ἔλμινς, a worm).—**DEFINITION.**—Medicines which kill or expel intestinal worms.

ENUMERATION.—The principal anthelmintics are:—Oil of Male Fern, Kamala; Kousso, Oil of Turpentine; Pomegranate Root, Worm-seed and its active principle, Santonin, Areca, Mucuna; Rue; and drastic purgatives. As purgatives only expel the worms, they are termed *vermifuges*; while the other anthelmintics which kill the worms are called *vermicides*.

ACTION.—The oil of male fern, kamala, kousso, oil of turpentine, and bark of pomegranate root, act as poisons to tape-worms, worm-seed and santonin kill round-worms, and also thread-worms. Castor oil, jalap, scammony, and other purgatives do not kill the worms, but dislodge and expel them, by the increased peristaltic action which they occasion.

USES.—Drastic purgatives may be used for worms of any sort; areca for both tape- and round-worms, and the other agents for the worms on which they severally act as poisons. Vermicides are generally given after the patient has fasted for several hours, in order that, the intestines being empty, the drugs may act more readily on the worms. A purgative is usually given some hours afterwards, in order to expel the dead worms. As thread-worms chiefly inhabit the rectum, they are most effectually killed by enemata, which may consist of a strong infusion of quassia; salt and water, vinegar and water, solution of sulphate, or of perchloride of iron; oil of turpentine; castor oil, decoction of aloes, or infusion of senna. As abundance of mucus in the intestines forms a convenient nidus for the growth of worms, anything that diminishes this tends to prevent their occurrence, and for this purpose preparations of iron and bitter tonics are useful.

T. LAUDER BRUNTON.

ANTHRAX (ἀνθράξ, a coal).—A synonym for carbuncle, and for malignant pustule. *See* CARBUNCLE, and PUSTULE, MALIGNANT.

ANTIDOTE (ἀντὶ, against, and δίδωμι, I give).—**DEFINITION.**—An antidote is any remedy which, by its physical or its chemical effect upon a poison, or in both ways, is capable of

preventing or counteracting the physiological effects of that substance. (*See* ANTAGONISM.) Sometimes, however, the term is used in a more comprehensive sense, so as to include the general treatment of a person affected by a particular poison. Thus, in poisoning by opium, the use of the stomach-pump, enforced exertion, chafing the limbs, and artificial respiration may be included in the general antidotal treatment.

MODES OF ACTION, AND APPLICATION.—Most antidotal substances form with the poison insoluble or innocuous compounds. Without attempting to give a complete list, the following are examples of the more common poisons and their respective antidotes:—(1) *Aconitine acid*: hydrated peroxide of iron, or light magnesia; (2) *hydrocyanic acid*: newly precipitated oxide of iron with an alkaline carbonate; (3) *oxalic acid*: chalk, common whiting, or magnesia suspended in water; (4) *tartar emetic*: tannin, catechu, or other vegetable astringents; (5) *acetate of lead*: sulphate of magnesia, or the phosphates of soda and magnesia; (6) *crustic potash*: dilute acetic acid, fixed oils, lemon juice; (7) *corrosive sublimate*: albumen, white of egg, flour, or milk; (8) *mineral acids*: chalk, common whiting, plaster from the walls or ceiling, or carbonate of magnesia; (9) *chloride of zinc*: albumen, milk, or carbonate of soda.

Vegetable poisons cannot thus be counteracted. If they have been taken in the form of seeds, leaves, or roots, the proper course is to remove them from the stomach or bowels as soon as possible by emetics and purgatives, and at the same time to sustain the flagging strength of the patient by the administration of stimulants. On the other hand, if the alkaloid has been taken, it is so soon absorbed that emetics and purgatives are of little avail, or may even be injurious. In these circumstances we must rely on the administration of the physiological antagonist of the poison (such as chloral hydrate in the case of strychnia-poisoning), and on supporting the strength of the patient. The following are the best antidotes to the vegetable poisons most frequently met with:—(1) *aconite root*: emetic of sulphate of zinc and stimulants; (2) *belladonna leaves or root*: emetic of sulphate of zinc, ammonia, stimulants, and after some time an active purgative; (3) *digitalis*: emetics, stimulants, and the maintenance of the recumbent position; (4) *hyoscyanine leaves*: emetics and stimulants; (5) *hydnoclorate or meconate of morphia*, or any of the preparations of opium: emetic of sulphate of zinc, external stimulation by warmth, turpentine or camphor liniments, enforced exertion, artificial respiration, and small repeated doses of sulphate of atropia; (6) *chloral-hydrate*: the same as for opium; (7) *strychnia or nux vomica*: animal charcoal suspended in water, repeated large doses of chloral-hydrate, or chloroform. *See* POISONS.

JOHN G. MCKENDRICK.

ANTIMONY, Poisoning by. *See* TARTAR EMETIC, Poisoning by.

ANTIPERIODICS.—**DEFINITION.**—Medicines which prevent or relieve the paroxysms of certain diseases which exhibit a periodic character.

ENUMERATION.—The chief antiperiodics are:—Cinchona-bark and its alkaloids—Quinine, Cinchonine, Quinidine, and Cinchonidine; Bebeeru-bark and its active principle, Bebeerin; Salicin, Salicylic Acid and its salts; Eucalyptus globulus; and Arsenic.

ACTION.—The mode of action of antiperiodics is at present unknown.

USAGE.—Cinchona, and still more quinine, is almost a specific in the treatment of intermittent fevers, periodic head-aches, neuralgias, and other affections caused by malaria. Though less certain in its action than in intermittent fevers, quinine is also the best remedy in the remittent fevers of the tropics, in which, however, it must be given in very large doses. The other alkaloids of cinchona have a similar action to that of quinine, but they are not so powerful. Bebeerin is only about one-third as powerful, and is by no means so certain; and the same remark applies to the other remedies enumerated. In some cases of ague and other intermittent affections arsenic proves successful when quinine fails. Emetics and purgatives are useful auxiliaries to quinine in the treatment of ague, and are employed alone for the cure of this disease in some parts of the world where quinine is not available.

T. LAUDER BRUNTON.

ANTIPHLOGISTIC (ἀντὶ, against, and φῆγμα, I burn).—A term for any method of treatment that is intended to counteract inflammation and its accompanying constitutional disturbance.

ANTIPYRETICS (ἀντὶ, against, and πυρετός, a fever).—**DEFINITION.**—Medicines which reduce the temperature in fever.

ENUMERATION.—The principal agents used as antipyretics are—Cold Baths, Cold Applications, Ice; Diaphoretics; Alcohol; Chloral; Quinine; Salicylic Acid and its salts; Eucalyptol; Essential Oils; Aconite; Digitalis; Veratrum; Purgatives; and Venesection.

ACTION.—The temperature of the body may be reduced, either by increasing the abstraction of heat, or by lessening its production. The direct application of cold, by means of baths, affusion, or sponging, or by enveloping the body in sheets wrung out of cold water, is the most powerful and rapid means of abstracting heat. But the loss of heat which constantly occurs, even in health, by evaporation of the sweat, and the radiation and conduction of heat from the skin, may be increased by the use of diaphoretics, such as salts of potash, preparations of antimony, or acetate of ammonia; or by such medicines as dilate the cutaneous vessels so as to allow the heated blood to circulate freely through them, and to become cooled by the external media surrounding the skin. Alcohol, in the form either of wine or spirits, and chloral, have an action of this sort, though alcohol also influences the production of heat. Alcohol, quinine, salicylic acid and its salts, eucalyptol, and essential oils lessen the production of heat within the body, probably by diminishing oxidation of the tissues. (See ALCOHOL.) Aconite, digitalis, and veratrum reduce the temperature,

but their mode of action is not precisely ascertained.

USAGE.—Antipyretics act much more powerfully in reducing the temperature of the body in fever than they do in health. They may be used when the temperature has risen either from exposure to a high external temperature, as in thermal fever; in consequence of inflammation, as in pneumonia, or pericarditis; or in specific fevers, as acute rheumatism, typhus, and scarlatina. The most rapid and powerful antipyretic remedies are cold baths; next probably come large doses of salicylic acid and quinine. The latter seems to act very efficiently in thermal fever when injected subcutaneously.

T. LAUDER BRUNTON.

ANTISEPTICS.—Antiputrescents (ἀντὶ, against, and σήματα, putrefying).

DEFINITION.—An antiseptic is a substance which prevents or retards putrefaction, that is, the decomposition of animal or vegetable bodies accompanied by the evolution of offensive gases. The putrefactive change occurs only in dead matter, and requires the presence of water, heat, and a ferment. That there is no putrefaction in the absence of water is obvious, for bodies, such as albumin and blood, which in the moist state are highly susceptible of putrefaction, may be kept for an indefinite time without change if they be perfectly dry. Heat also has an important influence on putrefaction. At very low temperatures the putrefactive change ceases, while elevated temperatures, such as prevail in tropical climates, are favourable to it. An additional element besides heat and moisture is, however, required, and the opinion generally accepted at present is, that this consists of minute vital organisms, which in some way excite putrefactive decomposition.

MODE OF ACTION.—The substances used as antiseptics act either directly on the bodies in which putrefaction is occurring or might occur, forming with them combinations that are not susceptible of the decomposing action of a ferment; or they act indirectly, by destroying the vitality or otherwise preventing the development and propagation of the organisms of which the ferment is composed. In this respect antiseptics are distinguished from disinfectants, the action of the latter being directed only towards the exciting causes and offensive or deleterious products of a class of changes which are themselves more comprehensive than those implied by the term putrefaction.

ENUMERATION.—There are numerous chemical agents possessing antiseptic properties, the chief of these including Chlorine, Sulphurous Acid, Nitric Oxide, and Peroxide of Nitrogen, as gases; Carbolic Acid, Cresols, Benzol, Sulphites and Hyposulphites, and the Hypochlorites, which emit vapours at common temperatures; Chromic, Boric, Tannic, and Salicylic acids, Permanganate of Potash, Sulphocarbols, Chlorate of Potash, Chloride of Zinc, and Charcoal, from which no vapour is emitted.

USAGE.—1. In therapeutic practice antiseptics are chiefly employed in the treatment of surgical operations and open wounds, to prevent the occurrence of putrefactive decomposition. Those antiseptics

ties are best suited for this purpose which, acting efficiently on the ferment, have little action, and no injurious effect, on the parts in which the healing process is going on. Gases, except in solution, cannot be readily used, as it would be necessary to enclose the substance to be preserved in an air-tight vessel containing the gas. The volatile antiseptics which slowly emit a vapour have been preferred to those which emit no vapour although among the latter salicylic and boric acids, being devoid of any irritating properties when applied to inflamed surfaces, would on this account present a marked advantage.

Carbolic acid has been used with success, a solution in water containing one part of the crystallised acid in from forty to one hundred parts of water being applied as a lotion, and also in the form of spray, diffused through the atmosphere during a surgical operation or the dressing of a wound. The carbolic acid solution may also be used on lint or cotton-wool for covering the affected part. Antiseptic gauze for a similar purpose may be made by adding one part of crystallised carbolic acid to five parts of common resin and seven parts of paraffin melted together, and applying the compound to coarse muslin, so as to form a thin coating of the plaster over the gauze, which, when it has hardened, is used for covering the parts to be protected. Professor Lister has also recommended a boric acid dressing for rodent ulcers, which is composed of boric acid and white wax, each one part, paraffin and almond oil each two parts. The boric acid and oil are added to the melted wax and paraffin, and the whole stirred in a mortar until it thickens, then set aside to cool and harden, after which it is to be rubbed in the mortar until it acquires the consistence of an ointment. This is thinly spread on fine rag and applied to the wound. The oil separates, and is absorbed by lint or rag placed over the dressing, while a firm plaster remains attached to the skin, which is easily removed when necessary. Salicylic acid may be substituted in this dressing for the boric acid. In some cases salicylic acid is applied alone, by merely sprinkling it in fine powder over the part affected. Its very slight solubility in water presents an obstacle to its use in solution, unless something be added to render it more soluble; and borax, which is itself a good antiseptic, may be used for that purpose. One drachm of salicylic acid, two drachms of borax, and half an ounce of glycerine, with three ounces of water, form, if aided with a little heat, a clear solution which may be used as an antiseptic lotion.

2. In medical practice antiseptics are also employed, either as local applications or as internal remedies. Those which are chiefly available include creasote, carbolic acid, the sulphocarbates, sulphurous acid, the sulphites or hyposulphites, chlorine water, permanganate of potash, borax or boric acid, chlorate of potash, charcoal, salicylic acid, and thymol. They are principally used for the prevention and treatment of infectious fevers; and in low forms of ulceration of the throat.

3. In using antiseptics for the preservation of anatomical specimens, a wider range of chemical agents may be taken, and a selection made of

substances that would be inapplicable in the treatment of the living subject. Arsenious acid, corrosive sublimate, or chloride of zinc in solution are of service for this purpose, and chromic acid, even when diluted with from five hundred to one thousand parts of water, possesses the property of preserving animal matter from decomposition, as also does a solution of one part of borax in forty parts of water.

Besides the more powerful antiseptics noticed, others of a milder nature, such as common salt, nitre, and sugar, are used for preserving articles of food; while alcohol and glycerine are employed for the preservation of animal and vegetable substances as specimens.

T. REDWOOD.

ANTISEPTIC TREATMENT is treatment directed against putrefaction, or rather, as now generally understood, against the development of fermentative organisms.

1. IN SURGERY, the employment of the antiseptic method is based upon the theory which attributes putrefaction and its consequences to minute organisms (bacteria, &c.) derived from without.

The treatment yields the most satisfactory results when it is so employed as to prevent, rather than to attempt to correct putrefaction. To obtain these results the surgeon must have unbroken skin to operate upon, or the wound must have been so recently inflicted that there has not been time or opportunity for the septic organisms to get beyond the reach of the antiseptic which he employs. Hence there must always be a percentage of failures in the treatment of compound fractures and large lacerated and contused wounds, owing to the amount of septic air and dirt carried into the recesses of the wounds between the time of the injury and the commencement of the treatment. In the event of putrefaction occurring in such a case, antiseptic dressings should be continued, but the question of operative interference must be determined according to the ordinary principles of surgery. Putrid ulcers and superficial wounds may certainly be rendered aseptic by suitable means, and so probably may cavities laid open during excision or amputation; but the attempt to correct putrefaction in deep sinuses, such as those connected with caries of vertebrae, is hopeless, though by appropriate dressings the putrid emanations may be rendered less noxious to the patient and those about him.

The antiseptics which have been found most suitable are carbolic acid, boric acid, chloride of zinc, and salicylic acid.

Carbolic acid is the antiseptic most generally useful. A solution of one part to twenty of water is employed to purify the skin of the part to be operated upon, the sponges, instruments, &c. A solution of one part to forty is used for washing sponges during an operation, for the hands of the surgeon and assistants, and for the changing of dressings. The volatility of carbolic acid renders it invaluable for dressing hollow wounds and abscesses. It is the active constituent of the ordinary dressing—antiseptic gauze, which is applied in eight layers, of size proportioned to the expected quantity of discharge, a piece of reliable thin mackintosh cloth (hat lining) being interposed beneath the outer layer of gauze; this serves to prevent the dis-

charge from soaking directly through the central part of the dressing, thereby washing out the stored up acid, and allowing the direct access of putrefactive organisms to the cavity. Disastrous consequences have followed from a defect in the mackintosh. A small portion of gauze wrung out of the one-to-forty carbolic acid solution is applied over the wound before the ordinary eight-fold dressing, so as to prevent possible mischief from putrefactive organisms accidentally adherent to the inner layer of the gauze, which might not otherwise be destroyed, owing to the slight volatility, at the ordinary temperature of the atmosphere, of the acid stored in the gauze. The gauze is also useful, on account of its antiseptic properties, as a bandage in retraction of the soft parts in stumps, and in any case in which free discharge is expected.

In addition to other measures, there must be an antiseptic atmosphere provided, so that the air which gains access to the wound or abscess may be innocuous. This is secured by means of a spray of one-to-forty carbolic acid solution, for the production of which Lister's portable steam apparatus may be used. When the spray is suspended during an operation or the changing of a dressing, the wound is covered with a piece of sound calico moistened with the same solution. Of course superficial sores and wounds require neither spray nor guard.

Cicatrisation is promoted by interposing between the healing parts and the antiseptic agent an impervious, unirritating protective layer, composed of thin oil-silk varnished with copal and then coated with a layer of dextrine, which allows the oil-silk to be uniformly wetted by the antiseptic solution into which it is dipped at the moment of application. The antiseptic dressing proper must extend a considerable distance beyond the protective layer, so as to prevent the access of putrefactive organisms beneath it.

Lint soaked in a one-to-ten solution of carbolic acid in olive oil is used as a dressing for abscesses near the anus, and occasionally as a stuffing for cavities. A one-to-twenty oily solution is smeared upon urethral instruments to prevent putridity of urine and its consequent evils.¹

Boric acid is a powerful antiseptic, but its non-volatility prevents its being used for the dressing of hollow wounds and in the form of spray. It is bland and unirritating as compared with carbolic acid, and is therefore particularly serviceable as a dressing for superficial wounds and sores. It is employed in the form of a saturated watery solution; as an ointment, in the proportion of one to six; and as boric lint, which contains about half its weight of the acid.

Chloride of zinc has the remarkable property of producing such an effect upon the tissues of a recent wound, that when applied once as a watery solution of about forty grains to the ounce, the cut surface, though not presenting any visible slough, is rendered incapable of putrefaction for two or three days, even when exposed to the

influence of septic material. The patient is thus tided over the dangerous period preceding suppuration, during which the divided tissues are most prone to inflammation and the absorption of septic products. Hence this agent, though not adapted for general use, is of the highest value when it is impossible to exclude septic organisms in the after-treatment, as, for example, after the removal of tumours of the jaws, in operations about the anus, and in amputations or excisions in parts affected with putrid sinuses, which should first be scraped out with the sharp spoon.

Sometimes a peculiar, disagreeable odour is observed on removing an antiseptic gauze dressing which has been applied for several days, especially to regions which have naturally a powerful odour, as the axilla or groin, and occasionally the odorous material is so irritating as to produce actual eczema around the wound. This seems to depend upon a reaction between the discharge or excretion and some ingredient of the gauze. *Salicylic acid* has the power of preventing this reaction, or, at any rate, of obviating or remedying its bad effects, if a little of the acid is smeared upon the protective or upon the inner layer of gauze. *Salicylic acid* has been introduced as an independent dressing by Prof. Thiersch, but has been found by Prof. Lister to be inferior to carbolic acid for the destruction of bacteria, though very efficient in preventing fermentations. *Chloral*, *thymol*, and *Eucalyptol* are used as antiseptics. Mr. Lister recommends gauze containing oil of Eucalyptus when symptoms of poisoning follow the use of the ordinary gauze dressing.

Prepared antiseptic catgut is employed for arresting arterial hemorrhage.

Chassagnac's drainage-tube is introduced to prevent tension after the opening of an abscess, or after the application of antiseptics to the raw surface of a hollow wound.

Carbolised silk sutures are used, as they are not liable to catch in the dressings.

2. IN MEDICINE, antiseptic treatment is based on the hypothesis that infectious and contagious diseases are caused by the presence and multiplication in the human organism of minute parasites, termed microzymes, microphytes, micrococci, &c. On this assumption, special remedies are administered for the purpose of destroying these minute organisms, or of rendering the blood and other tissues incapable of sustaining them. The treatment further aims at preventing the spread of these diseases by the prophylactic administration of antiseptic remedies to persons who are compelled to remain in infected places.

At present a definite relation would seem to have been made out between specific microphytes and cow-pox, sheep-pox, splenic fever, and relapsing fever respectively, whilst a similar connection has been so far supported by observations in the case of measles, scarlatina, diphtheria, enteric fever, and erysipelas; but much remains to be done before the true relation between microphytes and infectious diseases can be established. Seeing that antiseptic therapeutics depends on an unestablished etiology, it cannot be expected to be in a very advanced condition, accordingly there is at present but little that is settled or satisfactory to be said. The *sulphates*

¹ Cystitis, thus complicated with putridity of the urine, due to infection by catheters, may often be benefited by washing out the bladder with solution of boric acid. This complication of course never arises when the instruments have been carbolised from the commencement of the treatment.

and *hyposulphites*, introduced by Professor Polli in 1857, have been freely given in sybotic diseases in twenty-grain doses every three or four hours, and with apparently good effect.

Carbolic acid is also said to have been successfully used in diphtheria and in intermittent and eruptive fevers, in doses of from one to five minims or more.

The *sulphocarbolates*, introduced by Dr. Sansom in 1867, have been used with success in many diseases. They produce very little physiological effect, and seem to deserve increased attention. Dr. Brukenridge believed that he found sulphocarbolate of soda remarkably beneficial in an epidemic of scarlatina in 1875. Patients under ten years were given five grains, and those above that age twenty grains, every two hours. Also, according to this authority, the prophylactic effect of ten-grain doses three times a day was very striking.

Thymol and *saboeyle acid* have also risen into favour, owing to their powerful antiseptic effects being associated with comparative physiological inertness.

Sarcinous dyspepsia is greatly relieved and sometimes cured by Kuchmaul's method of washing out the stomach with solution of permanganate of potash, or some other antiseptic.

Reference must be made to solution of permanganate of potash, solution of carbolic acid, glycerine of borax or a preparation of boric acid of the same strength, sulphurous acid, and chlorate of potash, as applications to the throat in such diseases as diphtheria and scarlatinal tonsillitis, or in any form of sloughy ulceration of this part. To these may be added a five-grain solution of sulphate of quinine.

JOHN BISHOP.

ANTISPASMODICS (ἀντι, against, and σπασμα, a spasm).—DEFINITION.—Medicines which prevent or allay spasm.

ENUMERATION.—Antispasmodics may be arranged in groups as follows:—Valerian, Valerianic Acid and its salts; Musk, Castor, Asafoetida, Sumbul and Galbanum, Camphor, Bronninated Camphor, Oil of Amber, Ammonia and its Carbonate, Alcohol, Ether, Acetic Ether, Chloroform, Nitrite of Amyl; Bromide of Potassium, Bromide of Ammonium; Conium, Lobelia, Opium, Gelseminum, Indian Hemp, Belladonna, Stramonium; and the Essential Oils. As adjuvants may be mentioned—Cold Baths, moderate Exercise, Friction, Heat, and Moisture; and also Quinine, Arsenic, Zinc, and Silver.

ACTION.—Certain nerves and nerve-centres, when excited, produce contraction of voluntary or involuntary muscular fibres; other nerves and centres arrest movements; and by the combined action of these two systems the motions of the various contractile structures in the body are regulated, and subordinated to the requirements of the organism as a whole. Excessive contraction or spasm of one part of the body may therefore arise either from excessive action of the motor, or deficient action of the inhibitory centres. Spasm may affect the involuntary muscular fibres of the intestines—as in colic; of the vessels—as in some forms of headache, and in vaso-motor nervous of the uterus and bladder;

single voluntary muscles, or groups of muscles—as in various forms of cramp: or the muscular system generally—as in tetanus, epilepsy, and hysteria. Antispasmodics may act by lessening the irritability of motor centres, as, for example, bromide of potassium and conium; or by stimulating those portions of the nervous system which restrain and co-ordinate movements, as alcohol probably does. There are no direct experiments to show the action of antispasmodics on the inhibitory centres; but it seems probable that they have such an action, although it may not be confined to these parts alone. Thus small doses of alcohol and ether, which stimulate the nervous system generally, and usually increase motor activity, will restrain and co-ordinate excessive muscular action, as in colic, nervous agitation, trembling, and hysteria. It is at present impossible to localize the part of the nervous system affected by valerian, asafoetida, and other drugs of this class. As spasms occur when the nervous system is deficient in power, nerve and general tonics, such as quinine, zinc, and iron, are often found to be useful adjuvants.

USES.—In such convulsive diseases as epilepsy, laryngismus stridulus, and infantile convulsions, bromide of potassium is the most powerful antispasmodic; in hysteria—valerian, asafoetida, and the bromides; in chorea—arsenic, conium, copper, and zinc; in spasmodic asthma—lobelia and stramonium; in spasm of the blood-vessels—nitrite of amyl. In all spasmodic affections, cold baths or sponging, exposure to sunlight, moderate exercise, and a plain but nutritious diet should be employed; and late hours, a close atmosphere, exhausting emotions, or excessive bodily or mental work should be avoided. T. LAUNDER BRUNTON.

ANURIA—Absence of urination, whether from suppression or retention of urine. See MICTURITION, Disorders of.

ANUS, Diseases of.—The principal affections of this part are Congenital Abnormalities; Epithelioma; Irritable Sphincter Ani; Irritable Ulcer; Prolapsus; Prurigo; Tumours and Excrescences.

1. **Congenital Abnormalities (Atrisia)** may be classed as follows:—1. Imperforate anus without deficiency of the rectum. 2. Imperforate anus, the rectum being partially or wholly deficient. 3. Anus opening into a *cul-de-sac*, the rectum being partially deficient. 4. Imperforate anus in the male, the rectum being partially deficient, and communicating with the urethra or neck of the bladder. 5. Imperforate anus in the female, the rectum being partially deficient, and communicating with the vagina or uterus. 6. Imperforate anus, the rectum being partially deficient and opening externally in an abnormal situation by a narrow outlet. 7. Narrowness of the anus. These imperfections can be remedied, if at all, only by operation.

2. **Epithelioma.**—The anus, like other parts, where a junction takes place between the skin and mucous membrane, is liable to epithelioma. It is easily recognised by the ordinary characters of the sore. Warty growths and flaps of skin at this part are subject to this form of degeneration. The treatment applicable to this disease

is to destroy or remove the growth by caustics or excision.

3. Irritable Sphincter Ani.—In this complaint the anus is strongly contracted and drawn in by the action of the sphincter. Any attempt to examine the part produces spasm, and the finger passed through it is tightly grasped as if girt by a cord. In cases of old standing the muscle becomes hypertrophied, and forms a mass encircling the finger like a thick unyielding ring. This state is the source of serious trouble in defecation, owing to the expulsive power of the bowel being insufficient to overcome the impediment caused by the muscle to the passage of the faeces. Irritability of the sphincter occurs generally in hysterical females, and is relieved by mild laxatives, the local application of an opiate or belladonna ointment, and the occasional passage of a bougie coated with a sedative ointment.

4. Irritable Ulcer.—This is a small superficial sore, situated just within the circle of the sphincter, usually at the back part, commonly known as *fissure*, from its appearance in the contracted state of the part. The faeces passing over the sore excite spasm of the muscle, and cause a sharp burning pain which lasts for two or three hours. The distress often does not come on till an interval of ten minutes or more has elapsed after defecation. The pain is sometimes so acute that patients resist an action of the bowels, and allow them to become costive. The irritable ulcer occurs usually in middle life, and is more frequent in women than in men. It seldom gets well under the influence of local applications, but an incision through the centre of the sore sets the muscle at rest, and allows the part to heal. The French surgeons use forcible dilatation, so as to rupture the sphincter—a rough mode of treatment not to be commended. When the suffering is moderate, a cure may be attempted by giving a laxative to ensure soft evacuations; by enjoining rest in the recumbent position; and by the application of mercurial ointment with morphia, belladonna, or chloroform.

5. Prolapsus. See RECTUM, Diseases of.

6. Prurigo.—Itching, though a common symptom in disorders of the lower bowel, may occur as a distinct affection, a neurosis liable to paroxysms. It is caused by worms in the rectum, and by congestion of the hemorrhoidal veins. Patients suffer more after taking stimulating drinks and when heated in bed. The itching is extremely teasing and annoying, especially at night, keeping the sufferer awake for hours. Friction aggravates the mischief, excoriates the skin at the margin of the anus, and causes it to become dry, harsh, and leathery. As regards treatment, stimulants and condiments are to be avoided. The bowels should be regulated, and the part should be washed with soap and water after each evacuation. Every effort should be made to avoid friction. A piece of cotton wool soaked in oxide of zinc lotion should be kept applied to the anus, or the part may be smeared with some mercurial ointment, such as the dilute citrine, or one containing the grey oxide of mercury. Lotions of carbonate of bismuth and glycerine, of borax and morphia, or of carbolic acid, are often efficacious. In weak patients and anaemic men the cure.

7. Tumours and Excreescences.—Besides the flaps and folds of integument consequent on external piles, tumours of a *fibrous* texture sometimes form in the sub-cutaneous areolar tissue, which as they increase become pedunculated. They are usually small in size, lobulated, and have a firm feel. These growths may be easily and safely removed by excision. *Warts* are liable to be developed around the anus, and sometimes grow so abundantly as to constitute a large cauliflower-looking excrescence. They then form projecting processes of various sizes, densely grouped together, with their summits isolated, expanded, and elevated on narrow peduncles. They give rise to a thin offensive discharge. They originate in want of cleanliness. In some persons there is so strong a disposition to the formation of warts that it is difficult to prevent their growth. If few in number and small in size, they may be destroyed with strong escharotics. They usually require, however, to be removed by excision, the quickest and most effectual mode of treatment. Astringent lotions must afterwards be used to prevent the reproduction of the warts. Flattened growths from the skin, commonly called *mucous tubercles*, a secondary result of syphilis, are liable to occur around the anus. They yield readily to the local application of mercury and specific general treatment.

T. B. CULLING.

ANXIETAS.—Anxiety or distress, whether subjectively felt, or expressed in the features, attitude, or general behaviour. The term is also specially associated with a peculiar sensation experienced in the region of the heart. See PRÆCORDIAL ANXIETY.

AORTA, Diseases of.—The diseases to which the aorta is liable may be thus considered:—1. Aortitis, Acute and Chronic; 2. Atheroma; 3. Primary Fatty Degeneration; 4. Primary Calcification; 5. Coarctation; 6. Simple Dilatation; and 7. Aneurism.

1. Aortitis.—*Acute aortitis* is exceedingly rare. It may result from the direct irritation of an atheromatous aorta by a thrombus or an embolus, in persons of gouty diathesis; but has never been observed as an extension of acute endocarditis. The *morbid changes* consist in hyperæmia, with thickening and softening of the coats of the vessel, and deposit of fibrin upon its internal surface. The ascending portion of the arch is the part most frequently affected. The *symptoms* are acute substernal pain with oppression, palpitation, quick and feeble pulse, and elevated temperature. With these symptoms may be associated a harsh systolic murmur, originating at the seat of inflammation, and transmitted to a distant point of the aorta.

Sub-acute and Chronic Aortitis.—These are the usual forms of inflammation of the aorta. The disease may be general, arising from a blood-poison such as gout, from pyæmia, or from the various septic agents; but it is usually limited to a definite portion of the vascular surface, being the result of local irritation.

Ætiology.—Excessive and continued strain of the vascular walls is, according to its degree, the most frequent cause of sub-acute and chronic aortitis. Hence, the portion of the arterial system

most directly affected by the impulse of the left ventricle, namely, the arch of the aorta, is that in which inflammatory irritation is first, and often exclusively, exhibited. Labour of any kind requiring great and repeated muscular effort whilst the breath is held, must necessarily subject the aorta to extreme tension, partly through the obstruction arising from the pressure of the contracted muscles upon the subjacent arteries, and partly from the back-pressure of the distended veins. Hence, sledgers, rammers, ship-porters, &c., are those who most frequently suffer from the effects of aortitis. As a necessary result of such efforts the left ventricle soon becomes hypertrophied, and the evils arising from vascular tension are thereby proportionately increased. Furthermore, the free use of alcoholic stimulants, in which such labourers habitually indulge, contributes to the same result by imparting irritant properties to the blood. The British soldier has been especially liable to the evils above sketched, owing to a vicious system of forced drill with a breathing-capacity diminished by faulty construction of his dress and accoutrements.¹

ANATOMICAL CHARACTERS.—Sub-acute aortitis occurs in disseminated patches, and involves all the coats of the vessel. These are infiltrated with exudation-cells at an early period; become soft and tumid, assuming a bluish-white tint, and, owing to loss of normal elasticity, project outwards, thus causing unevenness or pitting of the internal surface. In the aorta the inflammation is usually primary; but exceptionally it may be produced by the mechanical irritation of an embolus derived from an inflamed focus. Inflammatory softening is a frequent cause of aneurism at all periods of life; and in the young it is the ordinary precursor of that disease.

In chronic aortitis, which is the most common form of the disease, the internal coat is alone involved. The outer portion of the intima exhibits the result of irritation in the abundant production of new cells. These cells occupy the fusiform spaces between its lamellae, and, gradually distending them, ultimately project the internal and unaffected portion of the tunic into the lumen of the vessel. The prominence so caused is comparatively solid, presents a faint bluish tint, and constitutes the condition described as 'fibroid or semi-cartilaginous thickening.' The inflammatory product is prone to undergo fatty degeneration, and the consecutive change called atheroma.

2. Atheroma.—This morbid condition is most common in the first portion of the aorta.

ANATOMICAL CHARACTERS.—Atheroma commences with inflammatory overgrowth by multiplication of the cells of the outer portion of the intima, as described in a preceding paragraph. The neoplasia, from their situation, readily undergo fatty change and caseation; the septa of unaltered tissue intervening between them soon lose their vitality and are absorbed; and the disease thus spreads, whilst it advances through the same agency towards the internal surface of the vessel. Examined microscopically, ather-

omatous matter is found to consist of fat granules, crystals of cholesteroline, and tissue-débris. At an early stage collections of this matter may undergo liquefaction, and, projecting into the vessel, covered only by a thin layer of the unaltered intima, constitute a so-called *atheromatous abscess*. Should this establish a communication with the artery, an *atheromatous ulcer* will be the result, and, consecutively, a false aneurism.

In the most advanced stage of atheromatous change many patches undergo calcification by deposit of lime-salts in the altered cells. The calcareous lamellae so formed, being concentric with the vessel, and contracting by loss of their liquid constituents, may erode the intima by their sharp edges. From the injury thus inflicted aneurism may arise, or interstitial thrombosis, by which the vessel may be entirely blocked and gangrene of the extremities produced. In consequence of the foregoing changes the vessel loses its elasticity and becomes dilated; its internal surface is mottled with yellow or fawn-coloured patches of various sizes, being also rough, spiculated, and fissured; and thus the condition described by Virchow under the name of *Enderteritis Chronica Deformans* is established.

The uric-acid and oxalic-acid diatheses favour these changes, not only by stimulating the minute arteries to contract, and so raising the blood-pressure in the larger vessels, but likewise by furnishing material for cretification. The subjects of constitutional syphilis are liable to 'ulcerated atheromatous' (atheromatous) changes of the intima.

3. Primary Fatty Degeneration.—Virchow has described, under the name of *fatty erosion*, a form of fatty degeneration of the cells of the internal coat, unpreceded by inflammation, commencing on the free surface, and gradually extending outwards. The internal surface of the vessel is marbled with minute yellow dots, which are groups of fatty cells; these undergo liquefaction; and disintegration of the internal coat, followed by aneurism, is the usual result.

4. Primary Calcification.—Exceptionally, in the distant portions of the aorta the muscular fibre-cells of the middle coat are liable to calcification, as a remote result of endarteritis. Owing to the transference of the calcified cells, fissuring of the middle coat under the pressure of the blood-current, and dissecting aneurism, are ordinary results of this change. Finally, the entire middle coat, and even all three coats of the artery, may be infiltrated with lime-salts as a primary change. This is most probably due to precipitation of these salts from the congested *vasa vasorum*, in consequence of the escape of their ordinary solvent, carbonic acid.

5. Coarctation or Stenosis.—This condition may be either *congenital* or *acquired*.

Congenital stenosis of the aorta is most frequently located at the point of junction of the *ductus arteriosus*, and is of very limited extent; in many cases presenting the appearance of a linear constriction, or of a perforated diaphragm. In a few examples, the vessel, at the seat of contraction, has been entirely closed and converted into a ligamentous cord. On the cardiac side of the constriction the aorta is dilated, and

¹ Also by the constrained and fixed position in which the walls of the chest are placed when the shoulders are forced backwards, with the view of producing the appearance of an expanded chest. - Ed

often thickened and atheromatous, whilst on the distal side it is reduced in calibre as far as the junction of the collateral vessels. Congenital stenosis of the aorta is compatible with life of moderate duration. In twenty-four out of thirty-eight cases analysed by Dr. Peacock the age attained varied from twenty-one to fifty years. The diagnosis of the condition rests mainly on disproportionate pulsation of the arteries arising from the aorta on the cardiac, as contrasted with those on the peripheral side of the obstruction, and on the enlargement of the collateral vessels, namely, the transverse cervical, internal mammary, and intercostals. The ordinary consequences are exhibited in dilated hypertrophy of the left ventricle, and inadequacy of the aortic valves. Death usually occurs from progressive debility and failure of the left ventricle; from pulmonary congestion; or from dissecting aneurism of the ascending portion of the arch. Congenital stenosis of the entire arch may result from imperfection of the inter-ventricular septum or patency of the foramen ovale allowing the blood to take an exceptional course.

In the *acquired* form, stenosis of the aorta at any portion of its course may result from inflammatory thickening or calcareous change of the coats of the vessel, followed by thrombosis; or it may follow the natural cure of an aneurism. The aorta may be much reduced in calibre without being disproportionately narrowed. Such will be its condition in connection with mitral inadequacy in early childhood, should the patient survive a few years. In such cases the left ventricle will have become dilated and hypertrophied, and a marked disproportion will be observed between the force of cardiac and that of radial pulsation. This circumstance, taken in conjunction with the age of the patient, the existence of disease at the mitral orifice, and hypertrophy of the left ventricle, would warrant the positive diagnosis of narrowing of the aorta.

6. *Simple Dilatation* of the aorta consists in a uniform enlargement of the vessel or of a portion of it, from impairment or loss of its normal elasticity; and depends primarily upon arterial obstruction or resistance beyond its seat, and directly upon consecutive hypertrophy of the left ventricle. The continued tension, to which the walls of the aorta are subjected between these two opposing forces, necessarily leads to progressive impairment of nutrition and loss of elasticity in its middle coat. The immediate consequence of this change is exhibited in further hypertrophy of the left ventricle; and its remote effects in still further impairment of nutrition and deterioration of tissue in the vascular tunics, through the increased tension to which they are now exposed. No elementary change of structure is, however, discoverable. Simple dilatation of the aorta commences in the ascending portion of the arch, and to this it is usually limited; but it occasionally extends into the transverse portion. The other portions of the vessel are never dilated, except in association with atheromatous change. The condition under notice is manifestly in close relationship with inflammatory irritation of the vessel. It has, however, a distinct pathological existence, ana-

logous to that of the early stage of vesicular emphysema of the lung.

No morbid results, with a single exception, are directly traceable to simple dilatation of the aorta. But, should the dilatation extend into the transverse portion of the arch, and engage especially its superior wall, the primary branches may become tortuous, and exhibit abnormal pulsation in the neck, simulating aneurism. In a noteworthy example observed by the writer the existence of this pulsation on *both* sides of the neck, and the facility with which it was arrested by forcibly extending the neck and shoulders, and so unbending the vessels, sufficed to establish the diagnosis. Tortuosity of the cervical arteries, dependent upon a local dilatation of the aorta, may be confined to one side of the neck.

Simple dilatation of the aorta most frequently occurs in connection with the contracted or granular form of chronic renal disease. It may, however, likewise arise from simple functional hypertrophy of the left ventricle dependent upon habitual vascular excitement; or from dilated hypertrophy consecutive to inadequacy of the aortic valves.

7. *Aneurism*—*Ætiology and Pathology*.—Aneurism of the aorta is essentially a disease of the middle period of life. Of ninety-two cases observed or analysed by the writer, sixty occurred between the ages of thirty and fifty years; twelve over fifty; and five under thirty years. Thus, whilst deterioration of the arterial coats as typified in atheroma is most common after the age of sixty, one of its ordinary consequences, aneurism, belongs to an earlier period of life. The apparent discrepancy may be explained by the more frequent employment of men under fifty in severe labour, and their greater capacity for extreme muscular effort then than later in life, the condition of the arterial wall which favours aneurism having been already established. Aortic aneurism is more common amongst males than females in the proportion of about 8 : 1—a difference no doubt due to the more active and laborious habits of the male sex. Soldiers, mechanics, and porters suffer from it in larger proportion than those of other callings; and in most instances the first symptoms of aneurism of the aorta may be traced to a great muscular effort involving vascular strain, or to a severe shock or blow, causing a direct contusion.

Aneurism of the aorta is always consecutive to disease of its coats. Inflammatory softening, atheroma, and calcification are the usual antecedent conditions, and in exceptional instances primary fatty or calcific transformation of the internal and middle coats, whilst a definite overstrain or a direct contusion of the vessel is frequently the immediate cause of the disease.

ANATOMICAL CHARACTERS.—Aortic aneurism may be presented under the following forms, viz., (a) *true*; (b) *false (circumscribed, and diffused or consecutive)*; (c) *dissecting*; and (d) *varicose*.

a. *True aneurism* of the aorta is rare; it may be either fusiform or saccular. It is essentially transitional, leading to the false variety of the disease; and differs from simple dilatation of the aorta only by its sharp limitation, and by

the existence of inflammatory products in its walls. True aneurism never contains clots, save by incidental thrombosis; and rarely, as such, attains dimensions capable of producing extrinsic symptoms or signs. It may, however, unlike simple dilatation, be the cause of valvular inadequacy, and so give rise to a murmur of reflux at the orifice of the aorta.

b. False aneurism is either *circumscribed* or *diffused*. *Circumscribed false aneurism* (or, as it is also termed, *false aneurism*) is the most common form of the disease in connection with the aorta. It is necessarily confined to a portion of the circumference of the vessel, the yielding of which relieves the remainder from extra tension. Hence, it is usually saccular in general outline, but, owing to unequal resistance at different points of its surface, it may, and commonly does, present one or more secondary prominences. The internal and middle coats are usually broken;—the adventitia supplemented by the surrounding structures more or less condensed, forming the sac.

Disintegration of the inner coat, already in a state of atheromatous change by mechanical strain or vascular tension, is ordinarily the immediate cause of false aneurism. The irruption of an 'atheromatous abscess' may also give rise to it, so likewise any ulceration of the intima from fatty erosion. Rupture of the coats of the vessel by mechanical strain is usually announced by definite symptoms of the utmost significance, namely, a feeling of something having given way within the chest or abdomen, followed by faintness often amounting to syncope, dyspnoea, palpitation, and occasionally hæmoptysis. These symptoms of shock usually subside within a period of one to two hours, but the patient is thenceforward incapable of his accustomed exertion, being easily put out of breath, and distressed by excitement or rapid movement, especially that of ascent, there is likewise a fixed pain at some point of the chest, back, or abdomen. A fusiform false aneurism may become 'invaginating' by abruptly expanding and ensheathing the artery at its proximal or distal side, or in both these situations.

Diffused false aneurism (or, as it is otherwise called, *Diffused aneurism*, or *Consecutive aneurism*) is produced by escape of blood from the artery, and its diffusion to a greater or less extent amongst the surrounding structures, according to their previous condition or anatomical arrangement. It may be the result of mechanical violence by strain or shock to the artery in a previously diseased condition; or of progressive disintegration of the sac of a circumscribed aneurism. In the latter case the diffusion of the extravasated blood is usually limited by antecedent adhesive inflammation of the surrounding parts, where, as in the transverse portion of the arch of the aorta, the position of the aneurism is favourable to that process. A case of this description recently came under the writer's notice. Under ordinary circumstances diffused false aneurism of the aorta cannot occur within the pericardium, owing to the isolation of that portion of the vessel, and the fragile structure of its serous investment. Hence, a yielding of the sac proper in this situation is, in most instances, followed

by instant death from hemorrhage into the pericardium and paralysis of the heart. In a few recorded cases, owing to previous adhesion of the pericardium, the patients survived rupture of the sac in this situation for several days.

Diffused false aneurism of the abdominal aorta is frequently formed by irruption of blood into the retro-peritoneal tissue, between the layers of the transverse meso-colon or the mesentery, or into the fibrous envelope of the psoas muscle. When the aneurism grows backwards the sac is quickly eroded by pressure against the vertebrae, the naked and curious surface of which then forms its posterior boundary. Diffusion in such cases rarely occurs until the vertebrae are entirely absorbed; the blood may then escape into the spinal canal, causing general paralysis and immediate death. Diffusion may also occur amongst the muscles and areolar tissue of the loins, or behind the diaphragm into either pleural cavity, usually the left. Any portion of the aorta outside the pericardium may be the seat of diffused false aneurism, but the transverse portion of the arch and the abdominal aorta are the parts most frequently affected.

Consecutive false aneurism, consisting in a primary bulging of all the coats of the artery, the internal and middle coats having subsequently given way, constitutes the ordinary form in which false aneurism originates: it therefore demands no further notice here.

c. Dissecting aneurism consists in a breach of the internal and middle coats, and a subsequent detachment of these from the external tunic, by the force of the blood-current, to a variable extent over the length and circumference of the vessel, or in a splitting of the middle coat by the same agency. This form of aneurism is of two kinds—that with a single aperture through which the blood enters the abnormal channel and returns to the artery; and that which exhibits two openings, one by which the blood escapes from, and another through which it re-enters the vessel. The former is the more usual variety of dissecting aneurism; and it is likewise the more grave, because liable at any moment to terminate fatally by rupture of the external coat.

Any portion of the aorta may be the seat of dissecting aneurism, the ascending part of the arch is most frequently affected, and next in the order of frequency comes the abdominal aorta. The primary lesion consists in a transverse rent of the internal and middle coats; when this is close to the heart, the outer or the anterior wall of the vessel is its usual site and detachment of the tunics rarely extends beyond the ascending portion of the arch, and seldom engages more than a limited area of its circumference. In this situation, too, an aperture of re-entrance is rarely formed, the disease usually terminating by rupture of the external coat within the pericardium. When, on the contrary, the second curve of the arch, or any portion of the aorta beyond this point, is the seat of primary lesion, separation of the coats is usually found to extend along the remainder of the length of the vessel, and over the whole or greater part of its circumference, whilst the blood has re-entered through an opening in one or both common iliac arteries.

The establishment of a second aperture of

communication with the artery is an attempt at 'natural cure;' and when this happens the patient may survive for many years. Amongst the eccentricities of dissecting aneurism may be mentioned detachment of the laminated clot from the walls of the sac proper, and subsequent escape of blood by rupture of the latter; and separation of the mucous from the muscular coat of the œsophagus, with irruption of blood into the stomach. Dissecting and ordinary false aneurism may coexist, the former being usually a consecutive lesion, and the immediate cause of death.

d. Varicose or Anastomosing aneurism consists in a direct communication between an aneurism of the aorta and (a) one of the chambers of the heart; (b) the pulmonary artery or one of its branches; or (c) one of the venæ cavae or innominate veins. This form of the disease is necessarily consecutive, and usually late as to the period of its development. In the great majority of recorded examples the primary aneurism was connected with the ascending portion of the arch, and in a large number it arose from one of the sinuses of Valsalva. The communication, with few exceptions, is formed with one of the chambers of the heart, the pulmonary artery, or the descending venæ cava. Of the cavities of the heart, the right ventricle is most often implicated; next in order is the right auricle; then the left ventricle; and lastly the left auricle. The pulmonary artery and the descending cava have been frequently involved, as might have been inferred from their close relationship to the ascending aorta; the innominate veins in fewer instances, and only when the aneurism engaged the upper portion of the arch. An aneurism of the abdominal aorta has communicated with the inferior venæ cava in a few cases. In the process of formation of a varicose aneurism of the aorta, the apposed surfaces are agglutinated by adhesive inflammation; and the composite septum is subsequently eroded by progressive absorption, or suddenly rent by the force of the arterial current. The immediate effects of communication are engorgement and increased tension of the receiving chamber or vessel; diminished blood-current and vascular tension in the aorta and its branches; and admixture of arterial with venous blood when the right side of the heart or one of the great veins is the seat of discharge. The special symptoms and signs by which the disease is characterised have direct reference to these results. Death has followed most rapidly in those cases in which the aneurism had established a communication with the pulmonary artery or the left auricle.

Effects upon the Left Ventricle.—Hypertrophy of the left ventricle cannot be regarded as a consequence of aneurism of the aorta. The association, when it exists, is accidental; hypertrophy depending upon antecedent or consecutive disease or inadequacy of the aortic or the mitral valves, chronic atheroma of the aorta, granular degeneration of the kidneys, or excessive functional activity.

Symptoms.—The symptoms of aortic aneurism may be discussed under the three heads of (a) Pain; (b) Excentric Pressure; and (c) Turgor.

Pain.—The pain of aneurism is of two kinds, *intrinsic* and *extrinsic*. The former is due to subacute inflammation and tension of the sac, and varies with intra-vascular pressure. It is dull, aching, and localised, and promptly alleviated by measures which depress the circulation or reduce local tension. Extrinsic pain usually arises from pressure upon adjacent nerves, and may be direct or reflex. This kind of pain has the characters of a diffused and aggravated neuralgia, being paroxysmal, and wandering to a greater or less extent over the back, chest, shoulders, arms, abdomen, and thighs. In the abdomen, when due to pressure upon the splanchnic nerves or tension of the solar plexus, it is of the most excruciating character. The extrinsic pain of aneurism may be fixed and boring. When of this character, it is usually located in the back, and arises from progressive absorption of the vertebrae.

Excentric Pressure.—The parts affected by the pressure of an aneurism, and the symptoms thereby developed, vary according to its situation and the direction of its growth. Parts which are exposed to counter-pressure, or are otherwise fixed, suffer most; whilst those which are flexible or movable are less injuriously affected. The symptoms have reference to the respective functions of the organs or structures pressed upon, whilst their severity is in direct proportion to the importance of those functions, and the degree of pressure exercised. Structures subjected to the remittent pressure of an aneurism are slowly removed by absorption, but between the sac and the resisting surface union has been previously established by adhesive inflammation. Hence the sac itself is at the same time absorbed, and escape of blood will inevitably occur where further resistance is not presented. When serous cavities are laid open by this process, entrance is effected by a rent; and if the cavity be large, e.g. the pleura or the peritoneum, death by hæmorrhage, almost instantaneous, is the result; in case of irruption into the pericardium or the spinal canal, death occurs with equal rapidity from compression and paralysis of the contained organ. Communication with a mucous canal or with the cutaneous surface is effected by a process of sloughing, and bleeding occurs by 'leakage,' in variable quantity and at uncertain intervals, till the slough is finally detached, when death by copious hæmorrhage immediately ensues. The irruption of an aneurism into a gland-duct, such as the ureter or one of the biliary passages, is fatal by obstruction and suspended secretion, the duct and its tributaries having been blocked by conglutium. Communication with the thoracic duct proves slowly fatal by inanition; and when an opening is effected into a vein, a varicose aneurism, characterised by special symptoms and signs, and of greater or less gravity according to its situation, will be the result.

The symptoms of nerve-pressure vary according to the nerves affected. Thus, pressure upon the roots or branches of sentient nerves is attended with neuralgic twinges or paroxysms referred to the seat of their peripheral distribution, and, when the pressure is extreme, with numbness in the same situation. Irritation of motor nerves is indicated by spasm or paralysis,

according to the degree of pressure, of the muscles supplied by them. Irritation of the cervical sympathetic, or of its cilio-motor roots, is revealed by dilatation of the pupil on the corresponding side: or, if the pressure be such as to cause paresis, by contraction of the pupil with ptosis, hyperæmia, hyperæsthesia, and elevation of temperature in the eye and corresponding side of the face. The effects of pressure upon the pulmonary and cardiac plexuses have been less precisely determined, owing to the difficulty of distinguishing the symptoms due to this cause from those which arise from direct pressure upon the trachea or bronchi, the great vessels, or the heart, or from structural disease of the heart or the coronary arteries: but that the paroxysms of bronchial spasm and of angina, so often witnessed in connection with aneurism of the arch of the aorta, are in some degree dependent upon pressure on the pulmonary and cardiac nerves, and occasionally are due to it exclusively, the writer entertains no doubt. The symptoms arising from the pressure of an aneurism upon the pneumogastric or recurrent nerve of either side have reference to the larynx, and are eminently characteristic. They are of two kinds according to the degree of pressure; namely, those due to spasm, and those to paralysis, of the laryngeal muscles on one or both sides. They are presented under the several forms of dysphonia, aphonia, stridor, metallic cough, and paroxysmal dyspnoea. The latter is frequently of the most urgent character, and sometimes is the immediate cause of death.

Adjacent organs, such as the heart, lungs, liver, and kidneys, are occasionally displaced by an aneurism, the direction being determined by that of the pressure, and in part also by the direction in which the organ is moveable. Obstruction or occlusion of adjacent arteries, as indicated by diminished or suppressed pulsation, may likewise result from the pressure of an aneurism. Pressure on a vein is evidenced by venous stasis distal to the seat of obstruction, upon the pulmonary artery, by engorgement of the right chambers of the heart and general venous congestion. Obstruction or occlusion of either bronchus or of one of its primary branches is evidenced by distress in breathing or shortness of breath; and by diminution or suppression of respiratory sound in the corresponding portion of the lung. Inasmuch as the symptoms of eccentric pressure may be produced by a tumour of any kind, they possess, in regard to aneurism, a diagnostic value only correlative to other and more positive evidence of that disease.

Tumour.—The tumour formed by an aneurism of the aorta is fixed, smooth, and compressible. It is alternately tense and soft in unison with cardiac pulsation, and is especially characterised by a movement of general and equal expansion, synchronous with the impulse of the heart. It is further distinguished by a remarkable liability to vary in the rate and direction of its growth, retrocession at one point coinciding with enlargement at another; a new set of symptoms being at the same time developed by its encroachment upon fresh territory. In the progress of cure the tumour may become solid, incom-

pressible, and uneven, by deposition of laminated fibrin within the sac.

Physical Signs.—The physical signs of aneurism of the aorta are those which may be elicited by *palpation, percussion, and auscultation*. They supply the most valuable, and, indeed, the only positive evidence of the disease.

Tactile signs.—The tactile signs of aneurism, *impulse, fremitus, and remittent tension*, are contingent on perceptible tumour. The impulse may be single or double. It is most frequently single, and is then always systolic in rhythm, coinciding approximately with the impulse of the heart. In character the systolic impulse is heaving and expansile, and it is diffused, in most instances equally, over the entire tumour. It is due to sudden expansion of the sac from active influx of blood during ventricular systole, hence, in those portions of the aorta which are close to the heart, it is synchronous with the apex-pulsation, but in the descending-thoracic and abdominal aorta perceptibly post-systolic in time. The force of systolic impulse and the expansion of the sac will be directly as the contractile power of the left ventricle, and inversely as the deposit of conglutium within the sac. A second and more feeble impulse of diastolic rhythm is occasionally, but much less frequently, exhibited by an aortic aneurism. This is the 'back-stroke,' or 'impulse of arrest' of authors. It coincides with the first period of ventricular diastole and the second sound of the heart, and is due to asynchronism of reaction between the aorta and the sac—that of the latter being notably later, owing to its defective elasticity. The consequence is a sudden arrest to the recoil of the sac by influx from the aorta. Diastolic impulse is therefore eminently characteristic of aneurism.

Fremitus or thrill is of more frequent occurrence than diastolic impulse, and, when not communicated from the heart, no less distinctive of aneurism. It accompanies the systolic impulse, and is due to the vibration of a thin sac from an eddy in the current of influx, produced either by a spiculated condition of the orifice, or by a pendent fluke of fibrin.

Percussion-sound.—The intrinsic percussion-sound of aortic aneurism is absolutely dull to the extent of the tumour. Posteriorly the dullness is not sufficiently distinguishable from that of the vertebral column and muscles to be of positive diagnostic value; whilst laterally and in front, when the tumour is not in actual contact with the walls of the thorax or abdomen, it is modified or masked by the intervention of the lung or the intestinal canal. Under any circumstances, dullness *per se* cannot afford positive evidence of aneurism, inasmuch as it may be due to a tumour of any kind, solid or liquid, in the same situation; but, the presence of a tumour having been determined, the shifting of percussion-dullness from one point to another, or its cessation where it had been previously detected, would be in the highest degree suggestive of aneurism.

Acoustic signs.—These are *loud or sound, and murmur*. *Sound* without murmur is of frequent occurrence in aneurisms of the arch, but comparatively rare in those of the descending-

thoracic and abdominal aorta. It is usually double, corresponding in time to the sounds of the heart, but exaggerated, the second aneurismal sound being especially intensified. The first sound is occasionally 'splashing,' and both are not unfrequently of a 'booming' quality, —characters no doubt due to the density, rigidity, and great capacity of the sac.

The murmur of aneurism is most frequently single, systolic, and blowing; it is occasionally double (systolic and diastolic), and still more rarely single and diastolic. As to quality, the systolic murmur may be accompanied by a musical note, 'cooing,' or shrill, and audible over the whole or only a portion of the tumour. Lastly, it may be, and usually is, of a 'buzzing' character in cases of varicose aneurism. The essential cause of the murmur of aneurism consists in friction of the blood against the orifice, and the production of an eddy or a 'fluid vein' within the sac. A certain force of ventricular contraction is, however, likewise necessary. Hence the not unfrequent coincidence of cessation of murmur with failure of the left ventricle for some time before death. A strongly contracting ventricle, a relatively small orifice, a capacious sac, and a liquid state of its contents, supply the most favourable conditions for the production of murmur. The orifice of entrance need not be absolutely narrow; a large fusiform aneurism, even of the true kind, with rough walls, and containing liquid blood, may yield a loud systolic murmur, as the writer has frequently witnessed. A murmur may be absent in an aneurism lined by thick laminae of fibrin through which there is a smooth channel, or in a lateral aneurism communicating by a small orifice with the vessel.

Diagnosis.—The positive diagnosis of aneurism of the aorta may be made from the existence of a tumour, forming a second centre of pulsation and of sound; the pulsation being systolic, expansile, and equally diffused over the tumour, accompanied by thrill, and succeeded by a minor pulsation of diastolic rhythm; whilst the sound, single or double, and accompanied or not by murmur, is always sharp and ringing, and occasionally of a 'booming' quality. The foregoing signs are rarely all associated in the same case. Various other groupings of rational symptoms and signs would be scarcely less conclusive as to the existence of aneurism of the aorta. General systolic expansion, thrill, diastolic impulse, and exaggerated sound, at a point more or less distant from the heart, constitute the most positive signs of the disease.

The existence of aneurism of the aorta may be inferred with greater or less confidence from certain symptoms and signs, according to their individual or correlative value. Even negative signs, if associated with others in themselves of minor significance, may be scarcely less conclusive than the most positive evidence would be. Thus, for example, suppressed respiration with percussion-resonance on the left side of the chest, dyspnoea, hæmoptysis, fixed pain in the back, and left intercostal neuralgia—the entrance of a foreign body into the left bronchus and the existence of cancer of the posterior mediastinum having been excluded—would be all but con-

clusive as to the existence of aneurism. A foreign body in the bronchus might be diagnosed from the history of a misadventure in swallowing, followed immediately by dyspnoea, hæmoptysis, and the special signs of bronchial obstruction, which, in nine cases out of ten, would be on the right side: whilst the diagnosis of mediastinal cancer would rest upon evidence eminently suggestive, namely, the presence of cancerous enlargements in the neck and axilla, and of extreme dulness over the root of the lung, without corresponding pulsation or sound. Finally, aneurism of the aorta may be, though it very rarely is, strictly latent in regard to both symptoms and signs.

Prognosis, Duration, and Terminations.—The prognosis of aortic aneurism is in the highest degree unfavourable. Recovery is, however, under favourable circumstances and appropriate treatment, quite within the range of medicine. Numerous examples of cure of aortic aneurism, both thoracic and abdominal, have been lately recorded.

The duration of life, in connection with aneurism of the aorta, has varied, according to the experience of the writer, from ten days to eleven years; but it may be much longer. The situation and relations of the aneurism, its complications; the constitution of the sac and the state of its contents, the previous health and present habits of the patient; and the advantages enjoyed in regard to rest and treatment—all all materially influence the prognosis, whether as to duration of life or prospect of recovery.

Death in aneurism of the aorta may result from—(a) rupture of the sac, (b) exhaustion from pain, loss of sleep, or leakage of blood, (c) asphyxia, (d) syncope, (e) inanition; or (f) intercurrent disease. The foregoing represents the order of relative frequency of the several causes mentioned. Rupture of the sac is not, of necessity, immediately fatal. Hæmorrhage may be stayed, and life thus protracted for several days, by obstruction from the extravasated blood, itself arrested and coagulated in the surrounding tissues, or by its pressure upon the aorta on the proximal side of the sac. Rupture into one of the chambers of the heart, the pulmonary artery, either vena cava or the innominate vein, the portal vein, or the biliary passages, is usually fatal within a very brief period; whilst rupture into one of the serous cavities in the absence of previous adhesion, into the trachea or bronchi, or into the alimentary or the spinal canal, is instantaneously fatal.

Treatment.—The treatment of aneurism of the aorta is *palliative* and *curative*. Pain from nerve-pressure is most effectually relieved by hypodermic injections of morphia, one quarter to half a grain in solution, repeated and increased in quantity according to necessity. The pain and oppression due to congestion of the sac and the surrounding structures is best treated by local or general abstraction of blood, combined with the use of cardiac and vascular depressants, especially iodide of potassium (20 to 30 grains every fourth hour), chloral hydrate (20 grains), and veratrum viride or aconite (5 to 10 minims of the tincture every third hour). Mechanical support by means of a well-constructed shield is likewise

useful when the tumour projects externally. Fixed pain in the back, due to erosion of the vertebrae, is most effectually relieved by a seton or issue in the vicinity of its seat. The curative treatment of aneurism of the aorta may be classified under the heads of—(a) compression of the artery, proximal or distal; (b) distal ligature; (c) absolute rest, with regulated diet; and (d) the use of medicinal agents promotive of coagulation within the sac. For the details of these several modes of treatment the reader is referred to the articles in this volume respectively intitled ANEURISM, ABDOMINAL ANEURISM, and THORACIC ANEURISM.

DESCRIPTION.—Aphasia is the name given to a defect of speech from cerebral disease, to which much attention has been paid during the last few years. When it exists the patient is found to be unable to utter any proposition, though his occasional distinct pronunciation of some one or two words shows that his speechless condition is not due to a mere difficulty in the more mechanical act of articulation. Moreover, the patient's intelligent manner and gestures may plainly show that he understands what is said, and is capable of thinking, even though he is quite unable to give expression to his thoughts. This kind of powerlessness as regards speech is most frequently encountered in persons suffering from right hemiplegia, though it is occasionally met with in those who are paralysed on the left side, and at other times in persons who are not hemiplegic at all.

The aphasic condition is not always, as it ought to be, clearly distinguished from another which may be encountered in association with hemiplegia on either side of the body, and to which the name *Amnesia* is given. The essence of this latter defect lies in the fact that the patient very frequently substitutes wrong words or names in the place of those he wishes to employ, as when speaking of his 'hat,' he calls it a 'brush;' or when seeking a 'pen,' he asks for a 'knife.' In a bad case of this kind the patient may be quite unable to arrange words into a sentence capable of conveying a definite meaning, so that his speech is rendered unintelligible. Where this species of defect exists there seems to be an inco-ordinate action of those higher cerebral centres whose function it is to translate thought into the corresponding motor acts of speech, so that we get hesitation and delay in the utterance of right words, or, what is worse, the substitution occasionally of entirely wrong words or even of a meaningless set of sounds

These amnesic or inco-ordinate defects were not at first recognised as being distinct in nature from those of an aphasic type, in which there is rather a loss than a misdirection of power in some of the higher centres, whence the incitation to the motor acts of speech proceed. The two kinds of defects, indeed, not unfrequently coexist to some extent in the same individual.

When occurring in association with hemiplegia, aphasia varies much in intensity according to the degree of general mental impairment with which it may be combined. During the first week or ten days after the onset of such an attack the special defect may be scarcely recognisable, owing to the masking influence of the general mental impairment. The patient lies, perhaps, in a restless but otherwise lethargic state, taking no notice of what is occurring around him, and not allowing his attention to be fixed even for a moment; so that there is at such a time no positive ground for concluding that he or she will subsequently manifest aphasic symptoms. But where recovery of general mental power begins to show itself, and the patient taking notice of what is passing around him, also attempts to reply to simple questions, the first signs of an aphasic condition may reveal themselves. He perhaps says 'yes' or 'no' to all questions indifferently; or if both words are used, it is inappropriately. Even in this stage, however, there may be defective power in the initiation rather than in the execution of many much simpler acts than those of speech. Attention to the nature of this defective power clearly shows that it is not occasioned by paralysis in the ordinary sense of the term. Thus a patient in this condition may not be able to protrude his tongue when simply told to do so, though it may come out with much readiness when a sweetmeat is applied to the lips, or even when he is shown rather than told what we want him to do.

After a time, however, such a patient may regain a considerable amount of general mental power, though he may be left more or less hemiplegic, and may also present the aphasic defect to a marked degree. He readily comprehends everything that is said to him, and can often understand what he reads. But at other times, as was the case with one of Trousseau's patients, though able fully to understand when read to, he does not seem to understand when he himself attempts to read. He can, perhaps, play draughts or chess well, and by means of gestures and pantomime can make his wants and most of his wishes fairly well understood by those accustomed to interpret them. Yet he may only be able to articulate some one or two words, or else combinations of mere unmeaning sounds, such as 'poi, loi, bah,' 'sapon, sapon,' or some other sounds which, doing duty on all occasions, constitute his only form of speech. On rare occasions, under the influence of strong emotion, the patient may blurt out some simple expletive or short phrase, such as 'oh dear!' Sometimes he can repeat a word which he has just heard uttered, though at other times he has no such power, and may even be unable to repeat, when told to do so, one of the stock words of

sounds to which he is accustomed to give utterance. In a few cases the patient has seemed unable to understand what is said, as though from some difficulty in realising the meaning of words. Words may have to be uttered very slowly and repeated several times to such a patient, and even then they may fail to convey their meaning. Yet the language of gesture, appealing as it does to the sense of sight, may be at once understood.

The patient's power of writing is necessarily interfered with when aphasia, as is so often the case, co-exists with right hemiplegia. Many such patients, however, learn to write with the left hand to a variable extent, though others continue powerless in this respect. The variations as regards the power of writing are, in fact, almost as marked as the variations in power of speaking, though these two classes of defects by no means run parallel with one another in the same individual. The writer has known a man who was quite unable to express himself in spoken words, write a fairly good letter with very few mistakes; on the other hand, the performance of such a patient, without a copy before him, may be limited to writing his own name. At other times the patient is able to write only more senseless combinations of letters; or writing some words correctly, he makes mistakes and substitutions with others—in fact, shows an amnesic defect in writing, and writes much as an amnesic patient speaks. Still more rarely it is found that an aphasic patient is, though not from want of manual power, unable to write even a single letter—in attempting to do so he makes mere unmeaning strokes.

Looking to the mode in which these symptoms most frequently group themselves, we find in one set of cases defects of an aphasic type only, as follows:—1. Loss of power, both of speaking and of writing (*Typical Aphasia*). 2. Loss of power of speaking, but power of writing preserved (*Aphemia*). 3. Loss of power of writing, but power of speaking preserved (*Agraphia*). At other times aphasic and amnesic defects are combined in the same individual, and then we may have—4. Loss of power of speaking, with an amnesic defect in writing. 5. Loss of power of writing, with an amnesic defect in speaking. Or, lastly, mere amnesic defects alone may exist in speech, in writing, or in both modes of expression.

PATHOLOGY.—The recent concentration of attention upon these defects of speech was started by the enunciation of Broca's views as to the dependence of the aphasic defects upon lesions in or about the third left frontal convolution. Subsequent investigations have in the main tended to confirm Broca's view as to the effects of injury to this convolution, though Meynert and others think that a lesion of the convolutions of the island of Reil on the same side is more frequently productive of aphasic symptoms. But all pathologists are now agreed as to the fact that lesions in or about the third left frontal convolution are much more prone to give rise to aphasic symptoms than are corresponding lesions on the right side of the brain. It is commonly believed, however, that amnesia may be induced by superficial lesions on either

side of the brain, and by lesions also which vary much in their topographical distribution.

Aphasia occasionally supervenes, independently of paralysis or convulsions, in individuals who have been subjected to great excitement or prolonged overwork, when it may be due, perhaps, to mere functional derangements. In other cases it presents itself as a temporary condition, lasting only for a few hours or a few days, in a patient who has just had an attack of right-sided unilateral convulsions; or, lastly, as has already been indicated, it occurs in conjunction with a right-sided hemiplegia produced either by brain-softening or by cerebral hæmorrhage. Cases belonging to the latter category vary very much amongst themselves as regards the degree of co-existing hemiplegia. If the third left convolution alone is damaged by softening, the hemiplegic condition may be transient and incomplete—never, perhaps, affecting the leg appreciably. This condition is often induced by a small hæmorrhage, or by a patch of softening produced by an embolism of that branch of the middle cerebral artery which supplies the third frontal convolution; but where the hæmorrhage is larger, or where the main trunk of the middle cerebral artery is obliterated, either by an embolism or a thrombus, the aphasia is combined with much graver and more persistent paralytic symptoms.

In some cases in which typical aphasia is met with, no actual lesion of the third frontal convolution is discovered after death. This is due to the fact that these symptoms may be occasioned by a lesion which, whilst not implicating the third frontal convolution itself, severs or interferes with the efferent fibres proceeding from this convolution to the corpus striatum, the next lowest nerve-centre; so that a lesion either of the part of the corpus striatum in relation with the third frontal convolution, or of the white matter intervening between the two, should be, and is found to be, as capable of producing aphasia as a lesion of the convolution itself.

The third left frontal convolution is not now supposed, as Broca put it, to be the seat of any 'faculty of language,' though the anatomical investigations of Meynert, and of Broadbent have shown that its relations with other convolutions are exceptionally complex. Whether or not certain assumed higher centres for speech are situated in this part of the brain, it must at least be conceded that this convolution is intimately concerned with the physical expression given to thought in articulate speech and in written language; it contains, in fact, the sites (or nerve-centres) from which the volitional incitations to these muscular acts usually pass downwards to lower centres.

We know that the left hemisphere is the one from which the volitional incitations proceed in the case of written language, and it is presumed that the same half of the brain also takes the lead in the production of articulate speech. It is, therefore, a point of much interest when we find that, in some of the exceptional cases in which aphasia has occurred in association with lesions on the right side of the brain and left

hemiplegia, the individuals had been left-handed during life. Some of the other exceptional cases, however, have not admitted of this interpretation, so that further observations are required.

TREATMENT.—Where aphasia occurs after excitement or overwork, without paralysis, it is a warning of much importance, since it may be the precursor of much graver symptoms. Unless such circumstances the patient requires an absolute cessation from work for a time, and most careful watching. Stimulants may need to be diminished, and bromide of potassium, with sambul and other sedative remedies, should be administered. Where aphasia is a temporary condition in association with right-sided convulsions, or where it is lasting and co-exists with right-sided paralysis, the treatment of the aphasic condition becomes merged in that of the associated convulsive tendency or paralytic condition, since, as a rule, an amelioration takes place in the patient's power of speaking coincidently with his improvement in other respects. This, however, is not always the case where aphasia has co-existed with a partial hemiplegic condition; the paralysis may be recovered from, whilst the aphasic defect remains more or less as it was. Where this is the case, an attempt should be made to teach the patient to speak again. Such efforts have occasionally been crowned with success (see *Trans. of Clin. Soc.*, vol. iii. p. 92), but much judgment and untiring patience have to be called into play in order to obtain satisfactory results.

H. CHARITON BASTIAN.

APHEMIA (ἀ, priv., and φημι, I speak).
See APHASIA.

APHONIA (ἀ priv., and φωνή, the voice) — Absence of voice, that is, of intoned utterance. See VOICE, Disorders of.

APHRODISIACS (Ἀφροδίτη, Venus) —
DEFINITION—Medicines which increase the sexual appetite and power.

EXCITEMENT.—The direct aphrodisiacs include—Nux Vomica and Strychnia, Phosphorus, Cantharides; Urtication and Flagellation; Cannabis Indica, Opium, and Alcohol in small doses. Iron and bitter tonics; meat diet; warm clothing, especially around the hips and loins; and abstinence from severe mental and bodily work act as indirect aphrodisiacs.

ACTION.—Aphrodisiacs may act by increasing the excitability of the nerves passing to or from the genital organs, or of the genital centre in the spinal cord (see ANAPHRODISIACS), as, for example, strychnia, nux vomica, and probably phosphorus, by causing irritation of the nerves of the genital or urinary organs or of adjoining parts, as cantharides and urtication; or by stimulating the brain, as Indian hemp or small doses of opium. Alcohol in large doses has a double action, increasing the sexual desire by stimulating the brain, while lessening the power of erection, probably by weakening the nerves through which the spinal centre acts on the genital organs, or depressing this centre itself. As the sexual passion becomes diminished when the nervous system is weakened with the rest of the body, and increases with returning strength,

iron with bitter tonics, and generous diet act indirectly as aphrodisiacs.

USKS—When the sexual functions are abnormally depressed, strychnia and phosphorus are the most generally useful of the direct aphrodisiacs. Cantharides, although sometimes valuable, must be employed with caution.

T. LAUNDER BAUNTON.

APHTHÆ—APHTHOUS ULCERS (ἄφθα, to inflame).—SYNON.: Fr. *Muguet*; Ger. *Fauch*.

DESCRIPTION.—In some states of debility and deranged digestion the tongue, together with the other parts of the mouth, becomes studded with small flakes, like morsels of curd, which are known as *aphthæ*. Sometimes these flakes extend and coalesce, so as to form large patches of thick, soft fur. This condition is particularly apt to manifest itself at the extremes of life—in infancy and old age—but it also occurs in the later stages of wasting or debilitating complaints. The white flakes can easily be detached, but, if this is done, they are soon reproduced. It is better, therefore, not to detach them, but to aim at removing the conditions which are essential to their existence. If they are forcibly detached, they are apt to carry the epithelium along with them, and to leave the papillæ raw; and these raw spots are prone to ulcerate. *Aphthous ulcers* have a very characteristic appearance. They are small, flat, and circular or oval; generally occurring in clusters, and, as it were, in successive crops. Their bases are soft and smooth, with a thin yellowish or greyish slough; their margins are well-defined and surrounded by a bright red areola, without thickening or elevation. They are commonly situated on the fore part of the tongue and the lips, where they are always accompanied by increased heat, and vivid congestion of the mucous membrane. At the same time there is generally

FIG. 1.—Oldham albuma.

active gastric or intestinal irritation, as well as fever of an atonic kind.

It was not till 1843 that the precise nature of these white patches was ascertained. In that

year it was shown by Gruby that they depend upon the presence of a microscopic fungus, to which he gave the name of *aphthaphyte*, or *cryptogame du muguet*. Subsequently this fungus was referred by Robin to the genus *oidium*, and by him called *oidium albicans*. It is found growing upon the tongue in close association with the epithelium. It forms delicate, horizontal filaments, which are apparently homogeneous in structure, and from which short articulated pedicels take their rise. The uppermost cells of these pedicels become expanded into oval bodies which fall off, germinate, and become new filaments. It is generally found growing in tangled masses, like minute bunches of mistletoe, mixed with the debris of scattered spores, cells of the *leptothrix*, and epithelial scales; but if separate filaments are followed out we may obtain such forms as those represented in Fig. 1.

Many ulcers are called aphthous which are really dyspeptic, and which owe their origin to stomatitis and irritation of the intestinal canal. The true aphthous ulcer, however, is always accompanied by the growth of the parasitic fungus that has been described above, and to such ulcers the term ought to be confined.

The treatment of this affection will be found described under THURSEN, a popular term which includes both aphthous and the dyspeptic ulcers resembling them.

Some writers speak of *aphthous ulceration of the vagina*, by which is meant a severe form of vaginitis attended by the formation of small ulcers resembling the aphthous ulcers. The *oidium albicans* is frequently met with in the vaginal secretion. W. FAIRIE CLARKE.

APHTHOUS.—A term applied to diseases in which aphthae are present.

APLASTIC (ἀ, priv., and πλάσσω, I mould).—Incapable of being organized, or of forming tissues, generally applied to inflammatory exudation.

APNEUMATOSIS (ἀ, priv., and πνέω, I breathe, respiration).—A synonym for Atelectasis. See ATELECTASIS.

APNŒA (ἀ, priv., and πνέω, I breathe), literally signifying breathlessness, is used by some medical writers as synonymous with asphyxia (see ASPHYXIA), the condition which supervenes on suspension or obstruction of the respiratory function.

By physiologists, and with more justice, the term is employed to signify the cessation of respiratory movements which is brought about by hyperoxygenation of the blood, as when an animal is made to breathe oxygen, or to breathe more rapidly than the needs of the economy require.

APOLLINARIS, Waters of.—Acidulous alkaline table-waters. See MINERAL WATERS.

APOPLEXY.—DEFINITION.—The word *apoplexy* means, by its etymology, a *striking from* (ἀπό, from, and πλάττω, a striking), and was at first and is still chiefly used to signify sudden abolition of consciousness and power of motion, which, in common English, is also called a *stroke*. Cerebral hæmorrhages being the most frequent cause

of this condition, 'hæmorrhage into the brain' and 'apoplexy' came to be used as synonymous expressions. Subsequently the effusion of blood itself was spoken of as *the apoplexy*, the word being used to designate the pathological condition causing the symptoms which it at first epitomised. Ultimately it was applied to a similar pathological state elsewhere, and thus hæmorrhages into the substance of the lung, the spleen, or the retina were, and still are termed respectively pulmonary, splenic, or retinal 'apoplexies.'

The term *cerebral apoplexy* is sometimes used to particularise hæmorrhage into the brain, but it is more commonly employed to denote an apoplectic condition depending on any cerebral lesion, and in that sense it will be here employed.

W. R. GOWKINS.

APOPLEXY, CEREBRAL.—SYNON.: A Stroke; Fr. *Apoplexie*, Ger. *Schlag*.

DEFINITION.—Loss of consciousness, of sensation, and of voluntary motion, coming on more or less suddenly, and due to a morbid state of the brain.

This condition of *coma* is termed 'apoplectic' when of sudden or rapid onset. Loss of consciousness may be due to other causes acting directly on the brain, such as defective or excessive supply or altered condition of blood; but it is customary to include among the forms of *apoplexy* only that sudden loss of consciousness which is due to cerebral congestion, and to consider as *apoplectic states* only those which result from distinct toxæmia.

ÆTIOLOGY.—The apoplectic condition may be due (1) to the influence upon the brain of a poison circulating in the blood; (2) to a sudden cerebral lesion, such as hæmorrhage or vascular obstruction, or (3) to a sudden shock or other impression arresting the cerebral functions, but causing no visible alteration in the brain.

1. The toxæmic states in which apoplectic symptoms occur are those of uræmia, drunkenness, and poisoning by narcotics, as opium, &c. These are described elsewhere, and need be referred to in this article only in respect to the diagnosis.

2. The great cause of apoplexy is a sudden cerebral lesion, which may be traumatic or may occur without external injury. Injury may lead to apoplexy by simple concussion, by laceration of brain, or by rupture of vessels and hæmorrhage. Apoplexy, not due to injury, may be caused by congestion; by thrombosis or embolism; but especially by hæmorrhage. The latter is its most common and most efficient cause. Profound coma is rarely due to any other spontaneous cerebral lesion. A very small hæmorrhage may cause apoplexy.

3. Lastly, apoplectic symptoms may occur without obvious lesion of the brain. The coma which results from concussion, that which succeeds an epileptic fit, and that which, in the absence of any recognizable cause, has been called 'simple apoplexy,' furnish examples.

PATHOLOGY.—In all these cases the apoplexy is in relation chiefly to the extent and suddenness of the lesion. Roughly speaking, its occurrence may be said to depend on the suddenness, its degree on the extent of the cerebral mischief. But the occurrence of apoplexy depends sometimes

on the size of the lesion, and the degree varies not only directly with the extent of the mischief, but with the extent of brain-tissue which is exposed indirectly to the irritative influence of the primary lesion. Hence position of lesion has an important influence in determining the apoplectic symptoms. For these several reasons apoplexy is especially profound when the hæmorrhage affects both hemispheres, either by simultaneous extravasation on each side, or as the result of hæmorrhage into the lateral ventricles.

The precise condition on which the apoplexy is immediately dependent has been a matter of dispute. It was formerly ascribed to the pressure exerted by the clot on the rest of the brain, either influencing directly the cerebral tissue, or pressing on and emptying its capillaries (Niemeyer). That such pressure is exerted by a large hæmorrhage is unquestionable. The convulsions on the side of the extravasation are flattened, and the falx is bulged to the opposite side (Hutchinson, Jackson). It cannot be doubted that the intensity of the apoplexy in these cases is due in part to this cause. But this will not explain the occurrence of the symptom in small hæmorrhages, by which no general pressure is exerted, or not more than is at once relieved by the displacement of the mobile fluid which surrounds the vessels. It will not explain its occurrence in laceration of the brain, or the early loss of consciousness in severe hæmorrhage, in which, as Jaccoud insists, it should, if merely due to pressure, be a late rather than an early symptom. There can be little doubt from these considerations, and from the cases in which there is no recognisable brain-lesion, that shock is an important element in the causation of apoplexy. Thus in cerebral hæmorrhage the apoplectic symptoms are due in part to the influence or the rest of the brain of the irritation of the nerve-elements by laceration. We can thus understand why vascular occlusion causes a slighter degree of apoplexy, since the immediate irritation of the local anæmia is less than that of laceration; and also why lesions of the pons produce as they do such deep and long-continued coma, since the irritated fibres are connected with, and thus influence indirectly a large part of the cerebrum.

Simple Apoplexy was a term given by Abercrombie to the cases, once thought to be frequent, in which apoplexy occurs without recognisable brain-mischief or blood-poisoning. Some of these cases were probably instances of uræmic poisoning, and others may have been due, as Dr. Bastian suggests, to capillary embolism. But cases are not infrequent to which neither of these explanations applies, in which death occurs in an apoplectiform attack, all organs being found healthy, and the brain only exhibiting, in common with the other organs, that passive congestion which results from an asphyxial mode of death. The nature of these cases is still mysterious, but they may be grouped with those in which fatal coma follows an epileptic attack, and is apparently due to the brain-shock produced.

Serous Apoplexy is a term applied sometimes to cases of fatal apoplexy in which no lesion discoverable except excess of serum on the surface of the brain. It is now understood that

such serous effusion is met with constantly in atrophy of the convolutions, rarely in Bright's disease, and under no other circumstances. There is no reason for associating its presence with the apoplectic symptoms. The cases described under this term were probably instances of uræmia, or of 'simple apoplexy' in old persons with atrophied brains.

SYMPTOMS.—The prominent feature of apoplexy is loss of consciousness without obvious failure of the heart's action. The onset is often instantaneous, so that the sufferer falls to the ground. The face may be flushed or pale—it is rarely very pale. The heart and arteries beat, often with undue force and lessened frequency. Respiration continues, but is laboured and stertorous, with flapping cheeks. The limbs are motionless. In severe cases no reflex action can at first be excited. The pupils may be dilated, contracted, or unchanged; in profound coma they are usually dilated; and they often vary in size spontaneously, being sluggish in their action to light. The patient can usually swallow, although often with difficulty. The sphincters permit the escape of urine and feces, or the urine may be retained. In a case of moderate severity the reflex action soon returns, the conjunctivæ become sensitive, and the patient can be roused to exhibit some sign of consciousness, shows returning power of voluntary motion, opens his eyes when spoken to, and tries, when told to do so, to protrude his tongue. On the other hand, the apoplexy may continue or may deepen in intensity, the patient dying at the end of a few hours or a few days. Death rarely occurs in a shorter time than two or three hours. In very rare instances an extensive hæmorrhage into the pons or medulla may stop the respiration and kill the patient in a few minutes.

It is not often, however, that there is this simple loss of cerebral function, uniformly distributed, and gradually deepening or passing away. Much more commonly the symptoms of a local cerebral lesion are added to those of apoplexy. Frequently such symptoms precede the loss of consciousness—unilateral weakness, deviation of the mouth, convulsion. They may be recognised during the attack: the limbs on one side exhibit more complete muscular relaxation than those on the other, they fall more helplessly when raised; or there is unilateral rigidity or clonic spasm, unvaried in its seat; or inequality of pupils is observed, or rotation of the head and conjugate deviation of the eyes. As the patient recovers, these local symptoms become more and more distinct, the tongue deviates on protrusion, speech and swallowing are difficult, or the patient may have lost the use of language.

In *inaggravated* apoplexy the commencement of the cerebral mischief is marked by symptoms of general shock, without any, or with merely transient, loss of consciousness. There is commonly pain in the head, and there may be other localising symptoms. After some hours, during which the patient may continue his occupation, coma gradually comes on and deepens into death. This form of apoplexy, first described by Abercrombie, is usually due to a slowly increasing cerebral hæmorrhage.

The temperature in cerebral apoplexy is at first

always lowered, but usually the fall is small, and is succeeded, after twelve to twenty-four hours, by a rise.

Diagnosis.—From the unconsciousness due to *cardiac syncope*, apoplexy is easily distinguished. In the former the heart's action fails, the pulse is weak and imperceptible, the face is very pale, the respiration is sighing and irregular, reflex action is rarely abolished, and the sphincters are seldom relaxed.

From the several forms of *toxæmia* the diagnosis is often easy, sometimes extremely difficult. It is easy when, on the one hand, the symptoms of apoplexy are preceded or accompanied by those of a local cerebral lesion; or when, on the other hand, the direct or circumstantial evidence of poisoning is clear, or the symptoms of toxæmia unmistakable. Where there are no local symptoms, and where no guiding history is to be obtained, the diagnosis is difficult, but a correct opinion may commonly be formed by an attentive comparison of the symptoms present.

There may be, as just observed, indirect evidence of toxæmia: the breath may smell of opium or alcohol; the urine may contain albumin. But albuminuria or a smell of spirits may mislead. Cerebral hæmorrhage often occurs after drinking; spirit is constantly given to a person in a fit. A smell of spirit must therefore only be allowed weight in the absence of any evidence of cerebral mischief. So, too, albumin is always present in the urine in uræmia, but it is also very frequently present in cases of cerebral hæmorrhage. Alone, this evidence of Bright's disease is of little value, except there be general œdema and the patient be young; then uræmia is more probable than vascular degeneration and cerebral hæmorrhage. But with other symptoms which indicate uræmic poisoning, albuminuria is conclusive.

The age of the patient should be considered. Late life is in favour of brain-disease. The history of a fall or blow on the head adds weight to other symptoms of cerebral mischief.

The character of the coma will sometimes guide. In uræmia, and commonly in alcoholism, it is less profound than in cerebral mischief. The patient can readily be roused. In apoplexy, in opium-poisoning, and in the most intense alcoholic poisoning, the coma may be profound. On the other hand, in cerebral hæmorrhage the patient, as Dr. Hughlings Jackson remarks, may sometimes be roused to answer questions. Violent struggling is strongly in favour of drink.

The mode of onset of the coma is important. In apoplexy it is sudden; in uræmia slow. The uræmic patient becomes first drowsy, then comatose. But with convulsions uræmic coma may come on suddenly. The onset of the coma of opium- and alcohol-poisoning is also slow. Ingravescens apoplexy is of deliberate onset, but a profound degree of coma is quickly reached.

General convulsions at the onset exclude drunkenness, and usually opium-poisoning, while they favour uræmia. Cerebral mischief sometimes commences with a convulsion, but the convulsion is then commonly unilateral, and one-sided symptoms are almost always afterwards to be recognised. Rigidity of limbs or local muscular twitching during the coma is, if constant in seat,

in favour of cerebral mischief; if variable in position, it is in favour of uræmia (Reynolds). Post-epileptic coma is of course preceded by a convulsion, and should be borne in mind.

The state of the pupils is alone of little importance. Great contraction occurs in and suggests opium-poisoning, but it is present in hæmorrhage into the pons Varolii. The pupils may be normal or dilated in uræmia, in alcoholic or opium-poisoning, and in apoplexy. Inequality of pupils, an unilateral symptom, points to brain-mischief. The retina should be examined, since the presence of albuminuric retinitis points, in the absence of the signs of a localised cerebral lesion, strongly to uræmia.

Lastly, the temperature should be noted. In uræmia there is persistent uniform depression; in cerebral lesions the initial depression is succeeded by a rise to a point above the normal.

The diagnosis of the *cause* of cerebral apoplexy will be described more fully under the heads of cerebral congestion, hæmorrhage, and softening. It may be here pointed out that slight and transient apoplexy, without local symptoms, with flushed face, and coming on during effort, points to cerebral congestion; slight and transient apoplexy with marked local symptoms points to softening; early and profound loss of consciousness to cerebral hæmorrhage. Post-epileptic coma may be distinguished by the history of epileptic attacks; or, if this be not forthcoming, it may be suspected if symptoms of local cerebral lesion or indications of toxæmia are absent, if the patient be under 40, and exhibits indications of speedy recovery. 'Simple apoplexy' cannot be diagnosed during life, since freedom from the symptoms of a local lesion does not afford ground for inferring that there is no such lesion.

Prognosis.—The prognosis in cerebral apoplexy depends in part upon the intensity of the attack. As long as unconsciousness is complete, and reflex action abolished, the patient is in danger of speedy death. The longer the apoplectic condition lasts without improvement, the less prospect is there of recovery. Persistent depression of temperature, or a rise of several degrees above the normal after an initial fall, are both of grave significance: such cases rarely recover (Charcot, Bourneville).

The nature, extent, and position of the cerebral lesion, when they can be inferred, furnish other prognostic indications. In hæmorrhage the prognosis is more serious than in softening. A sudden occurrence or increase of apoplectic symptoms, a few hours or days after a slighter attack, is always grave, indicating a fresh extravasation. If such apoplectic symptoms become profound and uniform, the prognosis is fatal, rupture into the ventricles or on the surface of the brain having probably occurred. If the localising symptoms point to a lesion of the medulla or pons, the prognosis is almost as unfavourable. Early return of consciousness and slight alteration in temperature are favourable signs. Previous cerebral disease renders the prognosis worse. Lastly, the prognosis must be influenced unfavourably by any impairment of the organic functions of circulation and respiration, whether independent of or due to the cerebral lesion.

TREATMENT.—The treatment of cerebral apoplexy must be guided by the indications of its cause. Where none can be obtained, it should be treated as cerebral hæmorrhage. Stillness is the most important condition. The patient should be moved as little as possible, but placed in the recumbent posture with the head slightly raised. The neck should be freed from constriction. If the extremities are cold, warmth may be applied to them, and cold to the head if there is local heat or flushing. Sinapisms to the neck and extremities sometimes seem to hasten the return of consciousness. The administration of stimulants should be regulated by the state of the heart. In thrombosis or embolism the heart should be kept up to the normal by very careful administration of alcohol, ether, or ammonia. In hæmorrhage it may be allowed to fall a little below the normal, but indications of failing power should be watched for and counteracted. Where no causal indication exists, the latter is the wiser plan. Venesection and purgation are remedies of similar effect, but different in degree, and are indicated by high arterial tension and cephalic congestion, shown by incompressibility of the pulse and flushing of the face. Venesection is useful where the heart acts strongly, and the pulse is full as well as incompressible. Its effect is proportioned to the rapidity with which the blood is taken, rather than to the quantity removed. Purgatives remove serum from the blood, and lessen the amount of blood within the skull by causing an afflux to the capacious intestinal vessels. The best purgative is croton oil. With a failing heart and pale surface they should be avoided. Diuretics may then be used to relieve the vascular tension. As the apoplexy clears, the nature of the case becomes evident, and the treatment of the several conditions is described elsewhere. (See BRAIN, Hæmorrhage and Softening.) For treatment of the other causes of the apoplectic state, see ALCOHOLISM, POISONING, and UREMIA. W. R. GOWERS.

APPENDIX VERMIFORMIS, Inflammation, Ulceration, and Perforation of.

DEFINITION.—Inflammation of the appendix vermiformis from lodgment of hardened feces or a foreign body, leading to ulceration, frequently ending in perforation of the coats; to inflammation and suppuration of adjacent tissues (perityphlitis); and to peritonitis, local or general.

ETIOLOGY.—The usual cause of this affection is a foreign body (*e.g.*, fruit-pips or -stones, a small bone, shot, pins, &c.); or a fecal concretion imprisoned within the cavity of the vermiform appendix. Perforation has been recorded in typhoid fever and tuberculous disease.

ANATOMICAL CHARACTERS.—Before perforation takes place the appendix may be found distended with pus, a foreign body or concretion lodged within it; and the mucous membrane ulcerated. The concretion or concretions vary in size from a small pea to a bean; are usually brown and hard; and consist of layers of condensed feces, secretions, and phosphates, deposited around a small nucleus, which may prove to be a seed or other foreign body, or a piece of unusually inspissated feces. These concretions greatly resemble, and are often mistaken for,

fruit-stones. Ulceration and perforation may occur at any part of the appendix, usually, however, at the extremity or the lower third. There may be a circumscribed peritoneal abscess; or the perforated part of the appendix may be found adherent to the surrounding parts, for example the cæcum or the abdominal wall.

SYMPTOMS.—Pain, generally ill-defined, in the right iliac region, may be the only symptom to attract attention, and, as a rule, it is not until local peritonitis or perityphlitis is set up that we may suspect the nature of the disorder; the absence of premonitory symptoms, of the characteristic tumour of typhlitis, and of intestinal obstruction, excluding inflammation of the cæcum. Often, however, the course from the first is latent, and the mischief is suddenly revealed by perforation into the peritoneum, followed by general and rapidly fatal peritonitis. Adhesions formed in front of the slowly advancing ulceration may localise the consecutive inflammation.

The substance imprisoned within the appendix may be dislodged by (a) inflammation and suppuration of the tissues around the cæcum (perityphlitis, pericæcal abscess); or (b) the appendix, at the point of perforation, having become adherent to the cæcum, a communication is established with this part.

DIAGNOSIS.—Inflammatory affections of the cæcum and of the appendix can rarely be clearly distinguished from each other. Inflammation of the appendix is apt to persist, continuing to be acute and severe; while cæcitis may be subdued by free relief of the bowels. Cæcitis with ulceration is apt to follow intestinal inertia; while the alarmingly acute and rapidly fatal symptoms of inflammation with ulceration and perforation of the appendix often arise during perfect health. Inflammation of the cellular tissue surrounding the cæcum (perityphlitis) is more commonly the result of ulcerative inflammation of the cæcum than of the appendix. The complete investment of the appendix by peritoneum contributes to perforation and fatal general peritonitis.

PROGNOSIS.—General peritonitis from sudden perforation into the cavity of the peritoneum is the great danger, recovery from which is extremely rare. Inasmuch as this may occur at any time during the course of ulcerative inflammation of the appendix, a guarded opinion should always be given when there is suspicion of the existence of this affection. Continued unconsciousness in the right iliac region without indications of fecal accumulation, or of inflammation in or around the cæcum, should not be regarded lightly. Though this serious accident is less apt to occur after the formation of adhesions around the advancing ulceration, we must not forget that well-marked local inflammation of the peritoneum, or of the cellular tissue around the cæcum, does not always prevent it, inasmuch as the adhesion which may thus form may not be sufficiently strong to withstand the pressure of pus in the appendix.

TREATMENT.—The patient must be kept at rest in bed, hot poultices applied, and an unirritating fluid diet allowed. Opium, for the purpose of relieving pain and subduing the peristaltic contraction of the intestines, should be freely and continuously administered; and if irritability of

the stomach exist, they should be introduced by enema or by subcutaneous injection. Peritonitis or other complications must be treated as they arise.

GEORGE OLIVER.

APPETITE.—In disease the desire for food may be either *lessened* or *increased*; or the appetite may be *perverted*, and a longing for various substances *unfitted* for or incapable of digestion may be displayed.

Loss of appetite—*Anorexia* accompanies almost all forms of acute or chronic gastritis; and as these affections constantly coexist with other diseases, great variety as regards the desire for food is manifested in various complaints. In acute gastritis there is often not merely a loss of desire for, but a positive aversion to food, and the patient resolutely resists any attempt at obliging him to take either solid or liquid nourishment. In the more chronic forms of gastritis the distaste for food may be only slight; in some cases the appetite is increased, but is quickly satisfied as soon as a small quantity of food is taken. In chronic ulcer of the stomach the appetite, as a rule, remains good, and the patient is only prevented from indulging it by the fear of the pain that will result from his so doing. Whenever the secreting structure of the organ is extensively diseased the appetite fails. Thus, in atrophy of the stomach the desire for food generally lessens along with the diminishing strength of the invalid. In cancer of the stomach there is always an extensive destruction of the glandular structure, and loss of the appetite is a constant and prominent symptom. It must be remembered that a loss of appetite may be more apparent than real. The physician is constantly consulted on account of this symptom, when a little inquiry will show that the patient is really digesting as much as his system requires, but that by a habit of eating without allowing a proper interval between his meals, or by indulging in food of too nutritious a nature, or in an undue amount of alcoholic stimulants, the sensation of hunger is prevented.

Increase of appetite—*Bulimia* usually occurs where there is a necessity for an increased supply of food. Thus it is common after all febrile diseases, where the stomach has been long inactive. Again, in diabetes, where a large portion of the food is passed off in the form of sugar instead of being converted into the material required to keep up the nutrition of the body, there is an unusually large appetite. A craving sensation is a common symptom in chronic catarrhal gastritis. It probably arises from the irritation set up by the mucus and fermenting substances long retained in the stomach, and is temporarily relieved by eating. The best treatment for such cases is to give alkalis about half an hour before the craving usually occurs, at the same time that the affection of the mucous membrane is combated by appropriate diet and remedies. In some persons the sensation of extreme hunger appears to arise from an irritable condition of the stomach, by which the food is passed into the duodenum before digestion is completed. The sensation is mostly complained of at night, and the writer has found it a good plan to let the patient have some beef-tea or meat lozenges.

for example, either just before retiring to rest or during the night. In children a craving for food is a frequent symptom, and arises either from the irritation of worms, or from chronic catarrh of the mucous membrane of the small intestines.

Perversion of appetite—*Pica* is most common in pregnant or hysterical females. Curious articles, such as chalk, cinders, and slate-pencil, are sometimes swallowed. In the insane and in idiots articles of an indigestible nature are not unfrequently introduced into the stomach, such as string, paper, cocoa-nut fibre, &c.

It is a matter of great importance that all persons, but especially dyspeptics, should accustom themselves to control their appetite. Whenever a larger amount of food is taken than the stomach is capable of digesting, the residue is apt to ferment and thereby to produce gastric catarrh. This is more especially the case where the digestive powers have been enfeebled by previous attacks of gastric inflammation.

S. FENWICK.

APYRETICS See ANTIPYRETICS.

APYREXIA (*h. priv.*, and *supra*, I am feverish).—This word literally means absence of fever: it is also used to denote the interval between paroxysms of intermittent fever.

ARACHNITIS.—Inflammation of the arachnoid membrane. See MENINGITIS.

ARCACHON, West coast of France. — Summer and autumn resort. Sheltered by pine woods. Calm in winter. See CLIMATE, Treatment of Disease by.

ARCUS SENILIS is a crescentic opacity of the cornea, within its margin, often seen in old people. The arcus is usually first observed in the upper part, and soon afterwards a smaller opaque crescent, opposite to this, appears below. In the course of years the two crescentic marks become slightly wider and more opaque, their points having at the same time extended much more considerably in proportion, so that an *annulus* or ring is formed. It probably is always widest and most opaque above, and wider and more opaque below than at the sides. An arcus is grey when it first appears, but it may attain at last to an ivory whiteness. It is especially noteworthy that arcus, besides being regular in shape, of an evenly-graduated degree of opacity, and well-defined at its inner margin, is never continuous with the opaque sclerotic external to it, but is always separated from this membrane by an extremely narrow line of demarcation of unaffected corneal tissue, which, as it is normally almost transparent here at its margin, is the more conspicuous by force of contrast with the new opacity. At the same time it must be observed that the well-defined opacity is most opaque in the centre or slightly external to the centre of its width, at any part; so that, although it is everywhere well-defined, it is shaded off somewhat abruptly towards its outer circumference, and more gradually at its inner margin. The arcus is much more prone to increase in opacity than in width. It rarely attains a width, even at the upper part of the cornea, of more than $\frac{1}{8}$ in. It is very conspicuous when backed by a dark iris. The cornea within the regular boundaries of the arcus senilis remains perfectly transparent, and vision is in no degree impaired by it. Wounds

in the part of the cornea thus affected heal well, and no surgeon is led by it to operate in any other part of the cornea, rather than divide the arcus itself in the part in which the corneal opening is made in almost all operations on the eye.

PATHOLOGY AND ÆTIOLOGY.—Arcus senilis is essentially a fatty degeneration of the proper substance of the cornea. It is not fully explained why it should appear just where it does, so near to the source of nutrition of the cornea, the fatty substitute for the natural tissues seeming to occupy only the circumference, and first and chiefly under the upper and lower lid, where also the conjunctiva and sclerotic overlap the cornea more particularly—a situation in which the lids exercise a certain amount of pressure, which has been regarded by Dr. C. J. B. Williams as the immediate cause of the degeneration.

If an eye suffers from chronic deep-seated disease an arcus will develop more rapidly; as, for example, in a case of old recurrent iritis of one eye only, in which there was a well-marked arcus, while in the other there was hardly a trace of it. An anomalous case is that in which the upper and lower arcus are opposite as usual, but in an inclined meridian. Arcus senilis is as capricious in its appearance as other senile changes; it is no clear indication of the age, certainly not of the number of years of life of a patient, as it may appear even in youth, and may never appear even in extreme old age, but when it occurs before forty years of age it is taken, by some life-insurance medical officers, to be an indication of concomitant fatty disease of the heart and degeneration of the arteries. But fatty heart is often found without arcus, and arcus without fatty heart. If, together with other evidence of weakened heart-power, there be an arcus, it is probable that fatty degeneration of the heart exists.

TREATMENT.—Arcus senilis is incurable, and no one endeavours expressly to check its increase, which, no doubt, is sometimes possible, as the writer is acquainted with a case in which the successful treatment of Bright's disease has, for ten years, completely arrested its advance.

J. F. SKEATFIELD.

ARDOR (*ardor*, heat).—A sensation of heat, burning, or scalding, which may be felt along the urethra during the passage of urine (*Ardor Urinæ*); or in connection with the stomach (*Ardor Ventriculi*).

ARGYRIA (*argyria*, silver)—The slate-coloured stain of the skin produced by the internal use of the salts of silver. See **PIGMENTARY AFFECTIONS**.

ARSENIC Poisoning by—Arsenic is classed as a metallic irritant poison, though its action is by no means limited to that of an irritant. It acts specifically on the gastro-intestinal mucous membrane, whatever be the channel by which the poison gains access to the system. The most usual source of acute arsenical poisoning is the administration of white arsenic or arsenious acid, but the sulphides, various arsenides, and impure commercial articles, such as dyes, wall-papers, and pigments, may be fertile sources of arsenical poisoning. Poisoning by arsenic may be either *acute* or *chronic*.

A. Acute Arsenical Poisoning.—This is the usual form of poisoning ensuing on the nefarious administration of any preparation of arsenic, but usually the oxide (*arsenious acid*) is employed.

SYMPTOMS.—The symptoms do not, as in the case of corrosive poisoning, come on immediately after the administration of the poison. There is most commonly an interval of half an hour or an hour between the swallowing of the agent and the onset of prominent symptoms. The quantity of the noxious agent, and its state as regards solubility, have also an obvious relation to the commencement of symptoms. Most commonly, after a sense of faintness and depression, intense burning pain is felt in the epigastric region, accompanied by tenderness on pressure. Nausea and vomiting quickly supervene, increased by every act of swallowing. Unlike what occurs in an ordinary bilious attack, with which arsenical poisoning may be at first confounded, the pain and sickness are not relieved by the act of vomiting. The vomited matters are extremely varied, and present no characteristic appearances. At first they usually consist of the ordinary contents of the stomach, but at a later stage are largely charged with bile which has regurgitated into the stomach in consequence of the violence of prolonged emesis, and they may be tinged with blood. Ordinarily vomiting is speedily followed by violent purging, and great straining at stool, the motions being often streaked with blood. Purging may, however, be entirely absent. Other prominent symptoms are great thirst, a feeble irregular pulse, and cold clammy skin. The patient as a rule dies within eighteen to seventy-two hours in a state of collapse; but tetanic convulsions are not uncommon, and even coma and paralysis may close the scene.

DIAGNOSIS.—From an ordinary bilious attack, induced by improper diet or by decomposing food, arsenical poisoning is diagnosed by the persistence of the symptoms after the removal of the apparent cause; and not infrequently by the symptoms remitting and again supervening on the administration of food or drink of a particular kind, or given by a particular hand. From choleraic diarrhoea it is distinguished by the sudden onset of symptoms, thirty to sixty minutes after food or drink has been taken; by the absence of rice-water stools, or of lividity of the skin; and by the symptoms not yielding to treatment. Moreover, in poisoning by arsenic there is usually greater tenderness over the epigastrium; the diarrhoea is less passive, and accompanied with more tenesmus than in choleraic diarrhoea, the stools are more often bloody; and nervous symptoms may be more pronounced. The diagnosis is, however, often very difficult, except when aided by a chemical analysis of the matters ejected from the stomach or of the excreta, which should always be made in doubtful cases.

PROGNOSIS.—This must always be uncertain, since it is rarely possible to ascertain the quantity taken, or to ensure its entire evacuation from the stomach.

TREATMENT.—Emetics, diluents, and demulcents are the appropriate remedies. The stomach-pump may also be usefully employed. In administering emetics, tartar emetic should be avoided, as it increases the depression, and its

presence complicates a chemical analysis. Moreover, tartar emetic frequently contains traces of arsenic, and, in the event of an analysis being made, an unfounded suspicion may be raised. No confidence can be placed in the so-called antidotes, *ferric hydrate* and *magnesia*, except where a solution of arsenic has been taken.

B. Chronic Arsenical Poisoning.—This form of poisoning is not uncommon, and is, unlike the acute form, generally accidental. The inhalation of arsenical vapours in factories, or of arsenical dust, as from green and other wall-papers, and in the process of manufacturing artificial flowers, is a common source of chronic arsenical poisoning.

Those who are chiefly exposed to this form of poisoning are persons employed in the manufacture of pigments, especially green pigments; paperhangers and decorators; artificial-flower manufacturers; milliners; persons exposed to the fumes of heated metals, particularly zinc and brass; manufacturers of dyes; and leather-dressers. In the process of deplating sheep-skins, previous to the tanning or the tawing process, a mixture of lime and orpiment (*sulphide of arsenic*) is used; and serious ulceration of the hands, scrotum, nose, and cheeks not infrequently results. Persons living in rooms the walls of which are covered with arsenical paper, especially bright-green papers containing arsenite of copper, are liable to suffer from chronic arsenical poisoning. It is uncertain whether this is entirely caused by the mechanical transfer of pigmentary dust to the air-passages, or is partly due to volatilisation of the arsenic, probably in the form of *arsenuretted hydrogen*. Many brown wall-papers also contain arsenic, and arsenious acid is sometimes added to the size; such papers have been known to produce the specific symptoms of arsenical poisoning.

That some persons can take arsenious acid internally with impunity in relatively large doses (*arsenic-eating*) is now a well-established fact.

SYMPTOMS.—The first symptoms of chronic arsenical poisoning are usually loss of appetite, præcordial pains, irritability of the bowels, and occasionally headache. Suffusion of the eyes, a peculiar and characteristic appearance of the conjunctiva, often amounting to actual conjunctivitis, and intolerance of light are early manifested. The muscular power of the limbs is impaired pretty constantly, and actual paralysis extending upwards from the lower extremities is occasionally observed. A characteristic vesicular eruption on the skin (*eczema arsenicale*) is frequent, as well as irritation of the skin, especially over the neck, scalp, hands, and armpits. Males who handle arsenical preparations are liable to ulcerations of the scrotum and penis, obviously due to a mechanical transference of the poison to the genitals when these are touched. If the source of the disease be not removed, progressive emaciation, exfoliation of the cuticle, and nervous prostration supervene; and convulsions may precede the fatal termination. The effects of green arsenical pigments are sometimes manifested by bleeding from the nose.

DIAGNOSIS.—When a patient suffers more or less from the symptoms above described, and is also known to be exposed to any of the sources

of danger from arsenical poisoning enumerated under the ætiology, the diagnosis is not difficult.

TREATMENT.—The source of poisoning should invariably be removed. It is found that those who suffer from working in arsenic make no progress towards recovery until they are removed from contact with the poison. Wall-papers which contain arsenic, and are suspected to be the cause of symptoms, should be taken away. Quinine, or other tonics, iron, and attention to the digestive organs will be needed. Removal to fresh country air is often productive of marked benefit. Soothing lotions to the skin, and careful attention to eroding ulcers, especially of the cheek, may be necessary. Shampooing and warm baths form the best treatment for paralytic lesions.

MORBID APPEARANCES.—These are the same by whatever channel the poison has gained access to the system. As a rule there is marked inflammation of the stomach and duodenum, usually of the small and large intestines also, but not uncommonly the inflammation is limited to the stomach, duodenum, and rectum, the intervening alimentary tract having escaped. If the poison has been administered in a solid form, white patches of the arsenical compound may be found imbedded in thick bloody mucus and inflammatory exudation. Portions of the white arsenic are also sometimes converted by the sulphuretted hydrogen evolved during decomposition into the yellow sulphide. Ulceration of the stomach is rare, and perforation almost unknown. An ecchymosed condition of the heart is often observed; and fatty degeneration of the liver, as in poisoning by phosphorus, has been described.

T. STEVENSON.

ARTERIES, Diseases of.—It is important to keep in mind the following anatomical facts in studying the morbid processes to which arteries are subject:—In immediate contact with the blood-stream in arteries lies the *endothelium*—a layer of flattened cells; outside this is the *tunica intima*, composed of elastic tissue in longitudinal arrangement; together the endothelium and tunica intima constitute the *internal coat* of the older writers. Still more external we find the *middle coat*, made up of muscular fibre arranged transversely, in the larger arteries mixed with elastic tissue, and, most external of all, the *external coat*, consisting of longitudinally fibrillated connective tissue.

1. **Acute Arteritis**, affecting a very limited portion of a vessel, and leading to ulceration, occasionally occurs. In some cases this has arisen from the irritation caused by an embolus, which, becoming detached from a cardiac valve, has blocked a distant artery, and Dr Moxon has specially drawn attention to its occurrence in the aorta, when the ascending portion of the vessel has been exposed to the impact of a hard, freely moving vegetation on one of the segments of the aortic valve. Dr. Moxon has also described, under the designation *inflammatory mollities*, the occurrence of softening and swelling of the arterial tunics in circumscribed spots; which become flabby and inelastic, and ultimately bulge outwards and form aneurisms. He believes that this condition depends on a peculiar general state, and is the great cause of aneurism in young, hard-

working men. Except in these circumscribed inflammatory lesions, we do not meet with any condition of the arterial tunics to which the designation acute arteritis can be applied. Such a change has, indeed, been described, and the writer has seen the lining membrane of the ascending and transverse portions of the aorta of a bright vermilion hue, strongly suggestive of acute inflammatory change; but the best observers are now agreed in believing that this appearance arises from staining by hæmatin.

2. Chronic Arteritis has been described as pursuing a course different from the *endarteritis deformans*, which will immediately be noticed; and as causing thickening of the coats of the vessels, narrowing of their calibre, and absence of pulsation during life. As such, chronic arteritis appears to be a disease of extreme rarity. But, on the other hand, if it be considered as the first stage of atheromatous disease, it may be said to be of frequent occurrence.

3. Periarteritis is the term applied by Charcot and Bouchard to the morbid change which, in their opinion, eventuates in cerebral hæmorrhage. According to these physicians, cerebral hæmorrhage is not usually due to atheromatous decay of the vessels of the brain, but, in the vast majority of cases, to the rupture of milary aneurisms, which in their turn have been produced by a morbid process beginning in the perivascular sheath surrounding the cerebral vessels, and which, proceeding from without inwards, ultimately involves all the coats of the vessels (see BRAIN, Hæmorrhage into).

4. Atheromatous Disease, the *Endarteritis deformans* of Virchow, is the arterial disease which is most frequently met with, and the one whose consequences are most serious. It presents three tolerably well-defined stages. (a) In the first stage we notice, when the vessel is slit open, greyish patches, by which the lining membrane is irregularly thickened; these patches seem to lie on the surface of the membrane, but this appearance is deceptive; the endothelium lies between them and the blood-stream, and is, at least at the beginning of the morbid process, unaffected. The material of which the patches are formed is really situated between the tunica intima and tunica media; it is semi-cartilaginous in consistence, and is formed by an abnormally rapid multiplication of the deeper cells of the tunica intima,—the new growth pushing up this tunic with its superimposed endothelium, and so causing a bulging into the interior of the vessel. The process is of the nature of an inflammatory change, that is, it consists in the proliferation of cellular elements, in consequence of some influence which has excited them to unnatural growth. (b) In the second stage the cellular elements of which the new growth is composed undergo a process of fatty degeneration; and in consequence it becomes yellowish in colour and pasty in consistence: it was the paste-like appearance of the mass in this stage which originally gained for the process the designation *Atheroma* (*ἀθήνη* = meal). It not unfrequently happens that the whole of the internal coat with its endothelium is involved in the softening, and gives way under the pressure of the blood, leaving an excavation, the floor of which is formed by the middle and external

coats of the artery. (c) In other instances, however, the pasty mass, instead of being washed away, becomes the seat of calcific deposit. This is the third stage in the process. The appearance of a vessel in which atheromatous disease has reached this stage is very striking: plates which present to the naked eye the appearance, but do not show the minute structure of bone, are observed at intervals in the walls of the vessel, and their sharp spicula project into its interior; in the aorta it is not uncommon to find such plates an inch long and half an inch broad, and in the smaller arteries the calcific matter sometimes forms a ring round the vessel. In the latter the calcareous particles appear to be deposited in the patch while it is still firm, so that the second stage of the process is wanting.

Atheromatous disease sometimes invades both the aorta and the small vessels, but the aorta may be extensively diseased and the small arteries unaffected; or, on the other hand, the cerebral, temporal, and coronary arteries may be the seat of calcific change while the great vessels are healthy, occasionally the disease is limited to a few vessels. Next to the aorta, the cerebral, coronary, and splenic vessels, and the arteries of the lower extremities, are prone to this form of arteritis.

EFFECTS.—The dangers to which an atheromatous state of vessels exposes the person in whom it exists are varied. The stream of blood is retarded by the projection of the new growth into the vessel, and still more by the destruction of the elasticity of its coats; and hence ensues a failure in the nutrition of the organ which depends for its supply of blood on the diseased vessel—this is said to be a cause of cerebral softening. When the paste-like mass is washed away it sometimes happens that the blood insinuates itself between the coats of the vessel, producing a dissecting aneurism; or the portion of the vessel, which has been weakened by the removal of the internal coat, yields to the pressure of the current, and a sacculated aneurism is originated; sometimes the diseased vessel bursts. Cerebral vessels, probably on account of the thinness of their walls, are especially liable to rupture when they are the seat of atheromatous change, and occasionally a diseased coronary artery has given way, filling the pericardium with blood. Arteries have been completely occluded by the deposition of fibrin on the spiculated edges of calcareous plates: this is one of the causes of senile gangrene; and embolic plugging of distant vessels at times results from the detachment of such fibrinous clots, and the washing away of atheromatous debris. Rigidity of the larger arteries from atheromatous change is likewise one of the most frequent causes of hypertrophy of the left ventricle of the heart, on which increased work is imposed in consequence of the destruction of the elasticity of the vessels. Aneurism has not, so far as the writer is aware, been mentioned by any author among the consequences of diseased arteries; but some cases which have come under his observation have led him to the conclusion that persistent aneurism, especially of the lower extremities in elderly men, is sometimes mainly due to a diseased condition of the arterial tunic. In the cases which he has observed there was

likewise present dilatation with hypertrophy and commencing fatty change of the left ventricle, itself a consequence of the arterial disease; but this seemed insufficient to account for the persistent oedema of the lower extremities.

Atherosclerosis.—The cause of endarteritis deformans is now generally admitted to be overstrain of the vessel. It was formerly thought that syphilitic impregnation of the system was a powerful favouring condition; but this opinion rested chiefly on observations made among soldiers, who, in addition to the syphilitic taint, were subject to other influences now known to be adequate in themselves to develop the disease, and the writer has himself seen the most extensive atheromatous disease in men in whom there was no trace of the syphilitic taint. Intemperate habits and gout appear to be powerfully predisposing causes; they probably render the blood impure, and its passage through the capillary vessels being thereby retarded, the tension of the arterial system is increased. Besides violent exertion, which imposes a strain on the entire arterial tree, there are other influences which act upon certain vessels. Thus the renal arteries are kept over-full in the erythritic form of Bright's disease, owing to the destruction of the capillary tufts, and hence atheroma of these vessels is almost constantly present in that form of renal mischief. The writer has on two occasions found extensive calcareous formations in the cerebral vessels of persons in whom cerebral degeneration had followed excessive anxiety and mental effort. The pulmonary artery is very rarely invaded by atheroma, and only in cases in which it has been kept in a state of tension by hypertrophy of the right ventricle or disease of the mitral orifice.

Diagnosis.—The diagnosis of atheromatous inflammation of the aorta will be discussed in a separate article. The existence of the disease in the arteries of particular organs can only be a matter of reasonable presumption when the patient is past middle life; when the ascertained causes of atheroma have been in operation; when symptoms of impaired nutrition of the organ are present; and when the organ (the brain or heart) is one the arteries of which are known to be prone to the disease. Calcification of the superficial arteries renders these vessels rigid and tortuous; the temporals when so affected attract the eye by their prominence, and may be felt hard and rigid beneath the finger; the brachial may equally be made the subject of examination; and, although the presence or absence of atheromatous change in such superficial vessels does not necessarily prove that the other arteries of the body are in a similar condition, it renders it more than probable that they are. Those who are not familiar with the resisting feel of the radial artery, when it is the seat of the change now under consideration, are liable to form a very erroneous estimate of the strength of the pulse; this may convey to the inexperienced finger an impression of a force which it does not possess. The error also is sometimes committed of inferring the existence of aortic regurgitation in these cases in consequence of the tortuous course and visible pulsation of the superficial vessels; but they do not collapse suddenly under the finger, as do the vessels during the receding wave in

aortic patency. The sphygmographic tracing, moreover, is essentially different. In atheromatous disease of the artery the upstroke is vertical, and the summit of the tracing extended. The existence of such evidence of vascular mischief affords a fair subject for consideration to those who are called upon to form an opinion as to the eligibility of a life for assurance.

Treatment.—The treatment of endarteritis deformans is mainly preventive. It consists in the avoidance of all those influences to which we have adverted as causes of the disease, namely, indulgence in alcohol, causes originating a gouty state of the blood, excessive muscular efforts, especially in constrained positions; postures which involve the long-continued contraction of muscles which surround arteries; and, as far as the brain and heart are concerned, all those states which favour overfulness of their respective arteries:—in the case of the brain, excessive mental application, deficient sleep, and, the writer believes, prolonged periods of sexual excitement; in the case of the heart, *inertia*, efforts which involve holding the breath, thus leading to distension of its right cavities, and imposing an obstacle to the return of blood from its walls.

5. **Fatty Degeneration**, unconnected with the atheromatous process, is sometimes, though rarely, found to affect arteries. Circumscribed opaque and velvety spots appear on the surface of the intima, and erosion ultimately occurs. Once this has taken place, the muscular coat, unable to bear the pressure of the blood-stream, fissures transversely, and the blood either ruptures the external coat, or, insinuating itself between the middle and external coat, produces a dissecting aneurism. This change has been found in the arteries of persons who seemed otherwise quite healthy; it is 'a morbid change which is simply degenerative from the first, and of whose immediate cause we know nothing' (Kindfleisch). Fatty degeneration of the external coat of the smallest arteries has also been noticed: it appears to be a senile change, and to play a part in the production of cardiac and cerebral degeneration.

6. **Calcification** of the arterial tunics also occurs unconnected with endarteritis, but more rarely than fatty degeneration. When this is the case, it is the middle coat of the smaller vessels that is the seat of the deposit, which consists of carbonate and phosphate of lime and magnesia. The process is usually limited to the vessels in which muscular fibre is abundant, but these it may affect extensively, the superficial vessels and the arteries of the brain and of the extremities being the favourite seat: it is eminently a senile change.

7. **Gummatous Disease** of the cerebral arteries in syphilitic patients has been described by Dr. Hughlings Jackson, Dr. Wilks, and others. The vessels present nodose swellings, and are thickened sometimes to three times their normal size by gummatous material infiltrating the outer coat; the calibre of the vessels is thereby narrowed, the formation of thrombi favoured, and cerebral softening produced. 'A random succession of nervous symptoms,' to use the words of Dr. Jackson, affords strong grounds for sus-

pecting syphilitic disease within the cranium; and the writer has himself seen three cases in which such symptoms disappeared under the use of perchloride of mercury and iodide of potassium, and in which it seemed to him that the supposition of arterial disease was much more probable than that of any other form of intracranial syphilis.

8. **Albuminoid Disease**, when it attacks the spleen or kidneys, appears first in the walls of the small arteries of these organs, but is not found in the larger arteries of the body.

9. **Contraction** and final impermeability of an artery from atheromatous calcification, from the accumulation of fibrine in its rough inner surface, from pressure, or from other causes, occasionally occurs, leading to gangrene of the extremity which it supplied.

10. **Dilatation** of arteries is in the majority of cases due to previous disease of their coats; but sometimes in the aged the arteries are found dilated without any degeneration of their tunics being present,—a state of affairs which Rindfleisch suggests may depend on atony of the muscular coat, and in some cases may possibly be connected with deficient innervation.

11. **Aneurism** receives full consideration in a separate article. Here it is merely necessary to point out the ways in which atheromatous inflammation and the other morbid processes which have been described contribute to the production of dilatation and aneurism. In some cases the course of events consists in the washing away of the diseased patch of the intima; when the middle coat either dilates, or, by separation of its muscular bundles, undergoes rupture, and the external coat yields before the pressure of the blood-stream. In other cases the dilatation occurs, not at the point where the endarteritis has invaded the vessel, but nearer to the heart. At the affected point there is narrowing of the canal of the vessel, and loss of elasticity in its coats; and as a consequence we have slowing of the circulation and deficiency in the supply of blood beyond, and increased arterial tension on the proximal side of the affected spot. The effect of this tension is more serious than would at first sight appear; in health the blood, propelled by each ventricular systole, enters contracted vessels, which, yielding before it, are uninjured by its sudden impact, but a vessel in a state of tension is exposed to the full violence of the column of blood discharged by the heart, and must gradually dilate before it.

12. **Arterial Disease in Insanity**.—According to Dr. J. Batty Tuke, and other physicians who have specially investigated the morbid changes in the brains of the insane, arterial disease is almost invariably present. It consists in such alterations as would result from obstruction in the ultimate ramifications of the vessels,—thickening of the proper coats of the arteries, and of the sheath of connective tissue which surrounds the cerebral vessels; the deposition of fine molecular matter and crystals of hæmatoidin between the adventitia and the sheath; and extreme tortuosity of the vessels.

13. **Arterio-Capillary Fibrosis** is the term applied by Sir William Gull and Dr. Sutton to the hypertrophy of the walls of the small arteries

found in the subjects of the cirrhotic form of Bright's disease. It is admitted by all observers of repute that the walls of the blood-vessels of the kidney are greatly thickened in this malady; but it is by no means so universally admitted that the small arteries throughout the whole body are in all such cases similarly hypertrophied. That they are hypertrophied in a certain proportion of the cases admits of no doubt; but the nature of the thickening remains to be decided. Dr. George Johnson, who early called attention to this condition, considers that there is present an hypertrophy of all the tunics of the small arteries, especially of the muscular coat—a consequence of the obstruction which impairs blood invariably meets with in the capillaries. Sir William Gull and Dr. Sutton, on the other hand, assert that the thickening is due to a fibroid growth, especially seated in the external coat of the vessel, and they believe that the coexisting disease of the kidney is not the cause of the arterial change, but that both are parts of a general diseased process. **JAMES LITTLE.**

ARTERIES, Examination of. *See* PHYSICAL EXAMINATION; and PULSE.

ARTHRALGIA (ἄρθρον, a joint; and ἄλγος, pain).—Pain in a joint. The term is more particularly applied to articular pain in the absence of objective disease.

ARTHRITIS (ἄρθρον, a joint).—A term generically used to signify any disease whatever involving a joint, but more correctly confined to articular inflammation. It is also employed to designate inflammation of all the structures forming a joint, as distinguished from mere synovitis. *See* JOINTS, Diseases of.

ARTHPODYNIA (ἄρθρον, a joint; and ὀδύνη, pain).—*See* ARTHRALGIA.

ARTICULAR RHEUMATISM.—Rheumatism affecting joints. *See* RHEUMATISM.

ARTIFICIAL RESPIRATION, or the method of exciting and keeping up the movements of the chest, so as to supply air to the lungs, is a subject of the highest importance, since the hopes of recovery depend on its due performance in many cases of narcotic poisoning, in the apparently drowned or asphyxiated, and in the collapse of the advanced stage of the condition induced by anaesthetics. For its effective employment it is essential to see that no foreign body obstructs the air-passages. Children and old people are liable to swallow large pieces of meat or crust, which become impacted in the pharynx or oesophagus. These should, if possible, be dragged away with the finger or a spoon-handle, but they may require the use of a probang. Tracheotomy is rarely necessary. A knife-handle held between the molar teeth is a ready and useful gag to keep the mouth open. A button-hook, in the absence of pharyngeal forceps, is sometimes very serviceable. Vomited matter should be quickly removed with a sponge or cloth twisted round a piece of wood. In treating the half-drowned the body should be inverted for a few minutes to favour the escape of water from the air-passages, but artificial

breathing should be commenced even whilst the body is in this position.

Merrison.—In most cases the best method of commencing artificial respiration is to compress the chest and abdomen simultaneously, then remove pressure so as to allow air to enter the chest, and again repeat the pressure every two or three seconds. If the sound indicates that air is passing into and out of the lungs, this method may be continued for half a minute; but if we are not sure that the air is exchanged, and in all cases if the patient's condition is not decidedly improved in half a minute, we should resort to:—

1. **Sylvester's method.**—Place the patient on his back on the floor, with a block or pillow under his shoulders, and raise the arms upwards above his head, by grasping them above the elbow, and pulling firmly and steadily as long as there is any sound of air entering the chest. Some arrangement is needed to prevent the body from being dragged towards the operator. For this purpose the plan of raising the chest on a high cushion or box has been adopted, but as a condition of cardiac anæmia is often present, this is objectionable. It is better to effect the object by placing a book in front of the thighs while kneeling at the head of the patient. It may be needful to draw forth the tongue, but generally if the head falls back over a cushion placed behind the neck, this is not required. An artery forceps, or a noose of string, or a handkerchief will enable an assistant to keep the tongue well forward.

As soon as the sound produced by the entrance of air into the chest ceases, the arms should be brought down a little towards the front of the chest, and pressed firmly and steadily against it for about one second after air is heard escaping. In cases of drowning it is enough to repeat this operation every four seconds, but in the collapse resulting from chloroform or other anæsthetics, the necessity for getting the vapour quickly out of the chest justifies a more rapid performance of the movements during the first five minutes. After this time the movements should be carried on more slowly, but they should be continued for half an hour at least, and even longer if the warmth of the surface and diminution of lividity gives any reason to hope that the heart has not entirely ceased to act.

2. **Marshall Hall's ready method** is performed by placing the body on one side, and alternately rolling it on its face to compress the chest, and on its back to allow the elasticity of the ribs free movement to draw air into the lungs. The plan is not nearly so effective as Sylvester's, but if no assistant is at hand it is the best mode of artificial breathing that can be adopted.

3. **Howard's method.** See RESUSCITATION.

4. **Mouth-to-mouth insufflation** is not to be depended upon, on account of the difficulty both of keeping the larynx open, and also of preventing the air going down the gullet.

Of the *instruments* introduced for the purpose of carrying on artificial respiration, mention should be made of those invented by Dr. Marcet and Dr. Richardson; but except in the hands of the inventors or of those who had gained much experience in their use by practising upon animals, the writer thinks they would do as much harm as good. The objection to them all is that they

interfere with the prompt imitation of the movements of respiration just described.

The administration of *oxygen* is indicated in most cases of artificial respiration, but the results of its use have not been satisfactory hitherto. Now that the gas can be had in a compressed state, and can be given by means of the laughing-gas inhaler, it is worthy of a further trial; but it is certain that in all cases of impending asphyxia time is of so much importance that anything which would delay the supply of oxygen would not be compensated for by giving it pure, instead of in the form of common air. Tracheotomy is not to be thought of in the first instance in any case in which air can be made to pass, even in very small quantity, through the trachea.

For supplemental and after-treatment, see RESUSCITATION. J. T. CLOVER.

ASCARIDES (*ἀσκαρίς*, a kind of worm).—This term, by long usage, is often employed to designate the very common intestinal parasite popularly known as *Thread-worms* or *Seat-worms*. Strictly speaking, these do not belong to the genus *Ascaris*, but to the genus *Oxyuris*. The fuller consideration, therefore, of their characters and clinical importance will be found under the Article *Thread-worms*.

Although the term as employed in the sense referred to is altogether erroneous, there are two true species of the genus *Ascaris* found infesting man. These are, respectively, the common round-worm or *Lumbricus* (*Ascaris lumbricoides*); and the moustached or margined round-worm (*Ascaris mystax*). Full particulars respecting the former will be found under *Round-worms*, whilst the consideration of the latter need only occupy a few words in this place.

Since the discovery and description of the *Ascaris mystax* as a genuine human parasite by the writer in 1868, six instances of its occurrence have been noticed at home and abroad, and there can be little doubt that the parasite is much more frequent in man, especially in children, than is commonly supposed. The writer has also shown that this parasite is identical with the *Ascaris mystax* in the cat, which, according to most helminthologists, is only a variety of the *Ascaris marginata* in the dog. The males are usually from 2 to 2½ inches in length; the females sometimes acquiring a length of 4 inches or more.

TREATMENT.—Like its congener, the falsely so-called *Lumbricus*, the margined round-worm readily yields to treatment by *santonina*. Two or three grains of this drug, followed by castor oil or a saline purgative, should be administered twice or thrice daily for a few days in succession.

T. S. COBOLD.

ASCITES (*ἀσκίς*, a leathern sac; a large belly).—**SYNON.**: *Dropsy of the peritoneum*; *Hydrops peritonæi vel abdominis*; *Hydropertoneum*. *Fr. Ascite*; *Ger. Die Bauchwassersucht*.

DEFINITION.—An accumulation of fluid within the cavity of the peritoneum, more or less serous in character, the accumulation being of the nature of a local dropsy, and not originating in inflammation. The amount of fluid varies much in different cases.

ÆTIOLOGY AND PATHOLOGY.—The chief matter

relating to the causation of ascites is to point out the morbid conditions by which it may be produced, as it almost always follows, and is a consequence of certain pre-existing organic diseases, of which it becomes a most important symptom and pathological phenomenon. The causes to which it has been attributed may be discussed according to the following arrangement:—

I. Direct mechanical obstruction affecting the portal circulation.

1. Obstruction of the trunk of the portal vein before it enters the liver, either from external pressure or internal obstruction.

2. Pressure upon or obliteration of the branches of the vein within the liver.

3. Pressure upon the trunk of the hepatic vein, or upon the inferior vena cava after it receives this vein.

II. Cardiac or pulmonary diseases obstructing the general venous circulation.

III. Disease of the kidneys.

IV. Morbid conditions of the peritoneum.

V. Miscellaneous.

I. Any direct obstruction interfering with the portal circulation must necessarily lead to congestion and over-distension of its tributaries, one of the consequences of which is excessive transudation of the fluid portion of the blood into the peritoneal cavity, while absorption is checked. The ascites is, under such circumstances, in short, merely a localised dropsy, resulting from mechanical congestion. The impediment may affect either the portal trunk before it enters the liver; its branches in the substance of this organ, or the hepatic vein or inferior vena cava near its termination.

1. The portal trunk may be pressed upon as it lies in the fissure, by prominences from the liver itself, enlarged absorbent glands in its vicinity, a neighbouring tumour (as cancer of the pancreas or a growth in the small omentum), a hepatic aneurism, or inflammatory thickening resulting from peri-hepatitis. The pressure may absolutely close up the vessel, but it more commonly causes a local clot to form, and thus its channel is blocked up. A thrombus is also in exceptional instances produced in connexion with a diseased condition of the portal vein, such as inflammation or calcification; obstruction to the circulation within the liver, or feebleness of the circulation, with an abnormal tendency to coagulation of the blood.

2. Pressure upon, or obliteration of the branches of the portal vein within the liver, can only arise as a consequence of some morbid condition involving the actual substance of this organ. The hepatic disease which by far most commonly leads to this result, and which is one of the most frequent causes of ascites, is cirrhosis. Occasionally it accompanies syphilitic and other forms of contracted and indurated liver, or it may be associated with infiltrated cancer. The extent of the obstruction thus set up will necessarily vary with that of the morbid changes in the organ. Occasionally a mass within the liver obstructs a considerable branch of the portal vein.

3. Obstruction of the hepatic vein or inferior vena cava is a rare event, but may arise from

the pressure of a growth connected with the liver itself, or of some neighbouring tumour.

II. Diseases of the lungs or heart which impede the general venous circulation must necessarily exercise a speedy and direct influence upon the hepatic circulation, and may thus lead to ascites. Usually, however, in cases of this kind the legs are the seat of considerable anasarca before peritoneal dropsy is observed. In course of time the continued congestion originates serious organic changes in the liver, its vessels being more or less obliterated, and consequently it is at this period that ascites is particularly liable to set in.

III. Ascites may constitute a part of the dropsy which so often accompanies renal diseases. It is, however, of comparatively infrequent occurrence to any great extent under these circumstances, the amount of fluid being not considerable as a rule, and the ascites being but a subsidiary part of a general dropsy.

IV. More or less serous effusion into the peritoneal cavity is a pathological result of peritonitis; but, in accordance with the definition of ascites given above, this does not come strictly within the present article. In exceptional instances, however, true ascites is observed as a sequel of peritonitis, in consequence of the morbid conditions which it leaves behind. Chronic peritonitis may also occasion a simple local dropsy, but this is particularly liable to be set up in connexion with morbid formations in the peritoneum, such as cancer or tubercle, of which the writer has seen striking examples. The immediate causes of ascites associated with diseases of the peritoneum may be—active congestion; implication of the capillaries or minute veins, or even of the larger veins, leading to mechanical congestion; obstruction of the lymphatic orifices, and consequent impaired absorption, or undue activity of the secreting structures.

V. Among the chief *miscellaneous* causes to which ascites has been attributed may be mentioned exposure to cold or wet; the sudden suppression of habitual discharges, or the rapid cure of chronic cutaneous affections; and extreme anæmia and debility. These causes are supposed to originate this symptom either by inducing active internal congestion; or by disturbing the renal functions; or in consequence of the abnormal state of the blood and tissues; but it is very doubtful whether either of them can actually of itself occasion ascites. Fluid may collect within the peritoneum as the result of the rupture of a cyst within the abdomen, especially an ovarian cyst.

It must be remembered that ascites may be due to a combination of two or more of the causes which have been indicated in the preceding remarks. For instance, there may be obstruction affecting the portal circulation within the liver and outside this organ at the same time; or the different organs may be involved simultaneously.

Predisposing causes.—Whatever tends to set up either of the morbid conditions which originate ascites, may be regarded as a predisposing cause. It may be met with at any age, but is most common during middle life. The hepatic form is much more frequent in

males than females. An anæmic condition of the blood and weakness of the tissues predispose to peritoneal dropsy, as they do to dropsy in other parts.

ANATOMICAL CHARACTERS.—The essential anatomical character of ascites is the accumulation of a serous fluid within the peritoneal sac. Its amount may range from a few ounces to some gallons. As regards physical characters, the fluid is generally thin, limpid, and watery in consistence; colourless or slightly yellow; clear and transparent; and of alkaline reaction. In exceptional instances, however, it may be coloured by blood or bile; or more or less turbid and dirty-looking; or of thicker and somewhat gelatinous consistence. Soft fibrinous masses occasionally float in the fluid, or these may form spontaneously when it is allowed to stand. Very rarely the reaction is neutral or acid. The specific gravity varies considerably. Chemically the fluid consists of water holding in solution albumin and the usual salts which are found in dropical fluids; but their proportion is very variable, though the albumin is generally in good quantity, which is evidenced by the degree of coagulation which takes place when the fluid is boiled. Occasionally it contains fibrin, cholesteroline, bile-elements, or, in cases of renal dropsy, urea.

The effects of the accumulation upon surrounding structures are to distend and macerate them more or less, or to compress them. Of course along with the ascites there will be the signs of any morbid condition upon which it depends; and there may also be indications of anatomical changes resulting from long-continued pressure of the fluid upon certain structures.

SYMPTOMS AND SIGNS.—Ascites usually sets in very gradually, being chronic in its progress, but advancing steadily. Occasionally, however, the fluid collects with considerable rapidity. The clinical phenomena associated with this pathological condition differ in different cases, both in their exact nature and their degree, according to its cause, the amount of the fluid, and other circumstances, but they may conveniently be considered under the following heads, namely:—1. *Physical signs.* 2. *Mechanical effects of the dropical accumulation.* 3. *General symptoms.*

1. *Physical Signs.*—Physical examination constitutes a most important part of the clinical investigation of cases of ascites, and it will be requisite to discuss the signs in some detail.

(a) If fluid collects in the peritoneum in any quantity, the abdomen presents more or less *general enlargement*. This is often the first change which attracts the patient's attention, and it may also have been noticed that the increase in size commenced below. The degree of enlargement depends upon the amount of fluid, but it may become extreme, so that the skin is tightly stretched and thin, presenting a smooth and shining appearance, or sometimes white lines are visible, due to laceration of its deeper layers. The umbilicus becomes affected in a characteristic manner, being more or less stretched and everted, and finally becoming obliterated, or in some cases more or less pouched out, and it may form a considerable prominence. Should there happen to be a weak portion of the abdominal wall, such as a hernial sac, this will boundedly pro-

truded. The important characters of abdominal enlargement due to uncomplicated ascites are that it is of a rounded form, though tending to be more prominent or to bulge towards the lower part or in the flanks, according to the posture of the patient; that it is quite symmetrical in shape, when the patient stands or lies on his back, but that the form alters considerably with a change of position, the abdomen becoming then more prominent in the dependent region, in consequence of the gravitation of the fluid in this direction, and it may actually be seen to move as the posture is changed. In contrast with the enlarged abdomen, the chest often looks small and depressed, and the fluid may cause its margin to become everted, or it may push forwards the xiphoid cartilage.

(b) The abdomen feels perfectly *smooth* and *even* over its entire surface. It usually gives a sensation of *tension* of the walls, without any hardness underneath. In some instances an obscure feeling of fluctuation is experienced on palpation with the fingers.

(c) The tendency of ascites is to interfere with the *abdominal respiratory movements*, if it is at all considerable, by preventing the diaphragm from acting properly. At the same time the writer has not uncommonly observed that, even in cases where the accumulation of fluid has been very considerable, abdominal respiration did not seem to be much diminished.

(d) *Percussion* affords some of the most important signs of peritoneal dropsy; and when the fluid is present only in small quantity, this is the only mode of examination that can lead to its detection. In the first place marked *dullness* is elicited over the seat of the fluid; while a tympanitic sound, which is often abnormally clear and distinct, is heard over the intestines. When there is but little fluid, it may be impossible to detect any abnormal dullness as the patient lies in the recumbent posture, but on placing him on his hands and knees, the fluid gravitates towards the front of the abdomen, and dullness may then be noticed in the umbilical region. In most cases, however, there is no difficulty in making out the dullness, and this sign is observed in those regions towards which the fluid naturally gravitates. Hence, when the patient lies on his back, the lower part and sides of the abdomen are dull, while its upper and front part is tympanitic. As more and more fluid collects, so the dullness increases in extent, gathering in, as it were, from below and from the sides, until finally the entire abdomen may be dull, except the umbilical region, which remains longest tympanitic. The boundary line between the dullness and tympanitic sound is usually well defined. As the posture is changed, so will the site of the dullness vary, the part which is undermost presenting this sign, while that which becomes highest is tympanitic; and thus the relative situation of these two sounds, as well as the shape of the dullness, can be altered in a variety of ways. When the patient sits up, the prominence between the recti muscles gives a tympanitic sound on percussion. In exceptional instances a distended colon gives rise to a tympanitic sound along each side of the abdomen, even when there is abundant fluid present.

Another important sign brought out by a kind of percussion is the sensation specially termed *fluctuation*, which is the peculiar wave-like movement realised on placing the fingers of one hand over one side of the abdomen, and flipping or tapping the opposite side with the fingers of the other hand. This sensation is very easily brought out if there is much fluid present, provided it is free to move, and sometimes the motion is actually visible. Change of posture will modify the seat over which fluctuation can be produced.

(c) *Auscultation* yields negative results in cases of ascites, there being no sound of any kind heard over the abdomen.

(f) In the large majority of cases ascites is clearly revealed by the physical signs already described. In exceptional instances, however, when the diagnosis is obscure, it is requisite to resort to a *digital* examination through the *rectum*, and in females through the *vagina*. The fluid collects in the recto-vesical pouch, and on examination per rectum, the finger detects the sensation of this fluid through its anterior wall. The vagina is usually felt to be shortened, while the uterus is pushed down and flexed. In extreme cases of ascites the posterior wall of the vagina, or even the uterus itself, may protrude through the vulva.

(g) Now and then it is requisite to make use of the *aspirator* or a *small trochar*, by the aid of which not only can it be determined whether fluid is present in the abdominal cavity, but its nature can also be ascertained. This method of examination is further useful when ascites is associated with some other morbid condition within the abdomen, which frequently cannot be made out so long as the fluid remains in the peritoneum.

It must be borne in mind that the ordinary physical signs of ascites will be materially modified or obscured under certain circumstances. For example, the quantity of fluid may be so small that most careful examination is required in order to detect its presence, on the other hand, it may be so abundant that dulness is observed over the entire abdomen, and fluctuation may be very indistinct. The existence of peritoneal adhesions—for instance, those which may be formed as the result of repeated *paracentesis*—also renders some of the most characteristic signs of ascites very ill-defined. Again, the association of peritoneal dropsy with some other abdominal morbid condition, such as a new growth, an enlarged liver or spleen, or an ovarian tumour, will also modify the signs elicited. The mesentery may be abnormally short, or the intestines may be adherent, thus being prevented from floating forwards, so that the usual relative positions of dulness and tympanitic sound are not observed.

2. *Mechanical effects of the dropsical accumulation.*—The clinical phenomena resulting from the mechanical effects of ascites are both *subjective* and *objective*. The patient often experiences a feeling of uneasiness and discomfort in the abdomen, as well as more or less tension and fullness, if there is much fluid present; while there may be a sense of fatigue and aching about the loins or abdominal walls. As a rule no

particular pain is felt, but colicky pains are liable to occur from time to time, and extreme distension of the structures constituting the abdominal wall may also cause painful sensations. In exceptional instances peritonitis is set up. When the fluid is abundant, the patient experiences its weight when he walks, and, during this act, he throws the head and shoulders back, at the same time keeping the legs apart. Symptoms connected with the alimentary canal are of common occurrence, but these are often to a great extent due to the same cause which originates the ascites, though the fluid must necessarily tend to interfere with the functions of the stomach and intestines. The bowels are usually constipated, but in some instances diarrhoea or dysenteric symptoms may arise. Flatulence is very commonly complained of, even a small amount of gaseous accumulation in the intestines being felt unuly, producing much discomfort, and increasing the enlargement of the abdomen temporarily. Occasionally vomiting occurs, in consequence of interference with the stomach. When considerable fluid has remained in the peritoneum for some time, it presses upon the inferior vena cava and prevents the return of blood through this vessel, and may thus lead to anasarca of both lower extremities, with enlargement of the superficial abdominal veins. Exceptionally the anasarca attracts attention at an early period. The flow of blood through the renal veins may also be obstructed, inducing mechanical congestion of the kidneys, with consequent diminution in the quantity of urine and albuminuria. In rare instances the fluid has been known to accumulate to such an extent as to rupture some part of the abdominal walls.

Ascites also frequently interferes with the thoracic organs. The lobes of the lungs are more or less collapsed, and the breathing becomes chiefly upper costal, while a sense of dyspnoea is experienced, especially in the recumbent posture and after taking food, the breath is short on exertion, and the respirations are often hurried and shallow. The heart is likewise liable to be disturbed in its action, as evidenced by palpitation, irregularity, or a tendency to faintness. This organ may also be displaced, so that its apex-beat is raised and too far towards the left, and in rare instances a basic systolic murmur has been originated as a result of this displacement.

3. *General symptoms.*—The general system is frequently seriously affected in cases in which ascites is a prominent symptom, but this usually depends upon the cause or causes which have originated the dropsy, though it may itself induce more or less debility, wasting, anæmia, and other general effects. The loss of fluid in this way has also been supposed to lead to deficient perspiration, and consequent dryness of the skin; as well as to diminution in the quantity of urine.

DIAGNOSIS.—The first matter bearing upon the diagnosis of ascites is to determine whether this morbid condition actually exists. The presence of fluid in the peritoneum, as well as its amount, can only be positively made out by physical examination, and in the great majority of cases the signs thus elicited are quite charac-

teristic. When the fluid is small in quantity, as well as under other circumstances in which the physical signs are obscured or modified, the diagnosis may be difficult and uncertain, but it may then be aided by a knowledge of the existence of some disease likely to give rise to ascites. That the accumulation of fluid is of a dropsical nature, and not due to acute or chronic peritonitis, is usually sufficiently obvious from the history of the case, and the collateral symptoms, while the local signs are also of a different character (*see* PERITONITIS, Inflammation of). The remaining abdominal enlargements from which ascites has to be most commonly distinguished are those due to flabby relaxation of the walls of the abdomen, combined with flatulence, accumulation of fat in the subcutaneous tissue and omentum; abundant subcutaneous edema, which may be associated with and obscure ascites; an ovarian tumour; or a pregnant uterus. Among the rarer conditions with which ascites is liable to be confounded may be mentioned colloid disease of the omentum; a greatly dilated stomach; distension of the uterus with fluid; great accumulation of urine in the bladder; a very large hydatid tumour, usually connected with the liver; extreme cystic enlargement of the kidney; and the so-called 'phantom tumour.' Most of these conditions are described in other parts of this work, and the limits of this article forbid any discussion of their several diagnostic characters; but a consideration of the history and existing symptoms of the case, combined with the results of a proper physical examination, constitute the data upon which the diagnosis is founded. It must be remembered that ascites may coexist with other morbid conditions in the abdomen, their physical signs being combined. Should there be an enlarged organ or other solid mass, it may often be recognised by making sudden firm pressure with the fingers over the abdomen, when the fluid is pushed aside, and the underlying resistance can be felt; or paracentesis may be performed, and further examination carried out after the evacuation of the fluid.

Another most important point in the diagnosis of ascites is to make out its cause. For this purpose all the facts bearing upon the case must be taken into account and carefully weighed, special attention being paid to the liver and the structures in its vicinity, to the heart, and to the kidneys. The amount of the ascites, and its relation to other forms of dropsy, afford considerable aid in the diagnosis. If it results from cardiac or renal disease, ascites always follows dropsy in other parts of the body, to which it is also generally subordinate; when it is due to hepatic or some neighbouring disease, the peritoneal dropsy appears first and is throughout most prominent. Should the vena cava inferior be obstructed at its upper part, anasarca of the legs will be observed simultaneously with, or even before the ascites.

PROGNOSIS.—The prognosis of ascites will mainly depend upon its cause; the amount of fluid present; the state of the patient; the condition of the main organs; and the results of treatment. In some cases this symptom is in itself attended with immediate danger, on account

of the mechanical effects of the dropsical accumulation, especially upon the thoracic organs, and still more if these organs are in a diseased condition. In other instances it aids in reducing the patient, and in thus bringing about a fatal termination. When ascites is due to local interference with the portal circulation, great relief can unquestionably be afforded in a considerable number of cases, and life may be prolonged by appropriate treatment; while, if the local cause is not such as in itself to lead to a fatal issue, the ascites may not infrequently be permanently cured.

TREATMENT.—The principles of treatment applicable to cases of ascites are (*a*), to attend to the condition upon which the dropsy depends, and thus endeavour to get rid of its cause; (*b*) to promote the absorption of the fluid; (*c*) to improve the constitutional condition and the state of the blood, if necessary; (*d*) to remove the fluid by operation, if absorption cannot be accomplished; and (*e*) to treat any symptoms needing special attention.

(*a*) As an important part of the treatment directed to the cause of ascites, particular attention must be paid to those organs which are most commonly accountable for this symptom, though unfortunately in a large proportion of cases but little effect can be produced upon the dropsy in this way.

(*b*) Absorption of the fluid is chiefly promoted by acting freely upon the bowels, skin, or kidneys. The class of remedies indicated will vary in different cases, and must be adapted to the state of the different organs, but as a rule active purgatives are most efficient in relieving ascites, especially when due to local causes, of which the most useful are compound jalap powder, cream of tartar, elaterium, calomel, gamboge, podophyllin, and croton oil. These remedies must, however be used with due caution. In some instances balsam or resin of copala has proved useful in the treatment of peritoneal dropsy. Assistance may be derived in certain forms of ascites from acting upon the skin by means of various diaphoretic baths. Digitalis and squills may be of service as diuretics; or the application of poultices of digitalis leaves over the abdomen is occasionally attended with benefit. The administration of iodide of potassium also seems to aid absorption in some cases.

(*c*) Treatment directed to the general condition of the patient, and to the state of the blood, is undoubtedly valuable in many cases of ascites. Tonics are often of decided service, and preparations of iron are specially indicated for improving the quality of the blood, if there is any tendency to anæmia. Not only do these remedies sustain the patient, but they may also have an influence in promoting the process of absorption. The diet must be adapted to the circumstances of the case, but usually needs to be of a nutritious character.

(*d*) In a considerable proportion of cases, however, no effect is produced upon the dropsical accumulation by any of the measures thus far considered. Then it becomes necessary to determine whether it is desirable to remove the fluid by operation. The fluid may be taken away either by means of the aspirator, or by the trochar and canula. The advisability of

having recourse to this plan of treatment must depend upon circumstances. The ascites is frequently not sufficiently abundant to justify paracentesis, and when the condition is of cardiac or renal origin, the operation can only afford temporary relief, so that there is no object in resorting to it unless the mechanical effects of the accumulation are such as to cause troublesome or dangerous symptoms, and it had better be delayed as long as possible. When ascites is a local dropsy, the fluid is often so considerable in amount as to necessitate its removal for the mere purpose of giving relief for the time. In cases of ascites associated with malignant disease, for instance, this is all that can be hoped for, as the fluid will certainly collect again. When, however, the condition is due to some local disease which is not in itself fatal, and especially to cirrhosis of the liver, the writer has found signal benefit result from the *repeated performance of paracentesis*, and has advocated this plan of treatment as a *curative measure*, so far as the ascites is concerned. Rarely does the operation give rise to any immediate ill-effects, and it is frequently found that remedies will act much more efficiently after the removal of the fluid than they did previously. In the writer's experience paracentesis repeated as often as the fluid re-accumulated has ultimately led to a complete cure in several instances; in others the cure was partial, a certain quantity of fluid remaining in the peritoneum, limited by adhesions; while in others still, life has been greatly prolonged, and much comfort afforded. The repeated accumulation does not seem to affect the system materially by reason of the drain upon it, and frequently not at all. Of course due care must be exercised in the performance of the operation, and in the subsequent treatment. In a few days after the removal of the fluid, the application of a bandage firmly round the abdomen, so as to exert even pressure, may prove of service in aiding the absorption of what remains, and preventing the recurrence of the ascites; and this measure may also be useful when a certain amount of fluid continues after the repeated performance of paracentesis.

(c) The symptoms resulting from ascites which are likely to require attention are those connected with the alimentary canal, dyspnoea; and cardiac disturbance, or a syncopal tendency. These should be treated on ordinary principles; but it must be observed that marked dyspnoea, if evidently due to the fluid, is an indication for the immediate performance of paracentesis.

FREDERICK T. ROBERTS.

ASIATIC CHOLERA. See CHOLERA.

ASPHYXIA (ἀ, priv., and σφύξ, pulse).—**SYNON.**: Apnoea; Fr. *Asphyxie*; Ger. *Erstickung*.

DEFINITION.—The term *Asphyxia*, though literally signifying *pulselessness*, is generally understood to mean the condition that supervenes on interruption of the function of respiration. The term *Apnoea*, preferred by many as a more exact one, has the disadvantage of being employed by physiologists in a totally different sense, viz. the cessation of the respiratory movements consequent on artificial hyperoxygenation of the blood.

There is therefore no advantage to be gained by substituting the term *apnoea* for the well-understood and older one, *asphyxia*.

ÆTIOLOGY.—Asphyxia may result from many causes which obstruct or interrupt the respiration. They may be divided into two categories, internal and external.

Internal.—These include paralysis of the respiratory nerve-centres by disease or injury of the medulla oblongata; paralysis of the nerves or muscles of respiration; a rigid fixation of the respiratory muscles; collapse or disease of the lungs; occlusion of the air-passages by organic disease or spasm of the glottis, pressure of tumours, and the like.

External.—To this group belong occlusion of the air-passages by foreign bodies; pressure on the chest not capable of being overcome by the muscles of respiration; closure of, or external pressure on, the air-passages, as in suffocation, strangulation, or hanging. These are all cases of obstruction of the respiratory movements in a medium capable of supporting life. To these external causes are to be added those conditions in which, though the respiratory movements are free, the surrounding medium is incapable of oxygenating the blood, viz. submersion in a liquid medium (drowning); or being surrounded by a medium devoid of oxygen, such as nitrogen or hydrogen. These gases have a purely negative effect, but many other gases which are classed as *asphyxiants*, such as carbonic oxide, sulphuretted hydrogen, chlorine, chloroform vapour, etc. have positive poisonous effects, and should therefore be called by some special name, such as *toxic asphyxiants*, to distinguish them from those which have no such properties.

PHENOMENA.—When an animal is placed in an atmosphere devoid of oxygen, or not containing a sufficient quantity of this gas (under 10 per cent) to maintain the respiratory process, or if the mechanism of respiration is simply obstructed, it begins to show signs of agitation and to make powerful inspiratory and expiratory efforts, in which the accessory muscles of respiration are all brought into action; the arterial tension increases; and the superficial veins become distended and livid.

After a variable period these dyspnoic efforts pass into general convulsions, in which the muscles of expiration are more especially in action, during which the splinters are forced and the excretions voided. On these there follows a calm, during which the animal lies insensible, with dilated and immovable pupils, and with reflex excitability abolished generally. All muscular movements cease except those of inspiration, which are repeated at intervals. As death approaches the respiratory movements become shallower and less regular, and are succeeded by stretching convulsions, during which the back is straightened, the head is thrown back, the mouth gapes, and the nostrils dilate. The heart still continues to beat after other movements have ceased. The heart ultimately stops in the state of diastole. Death is then complete and final.

COURSE AND TERMINATION.—The time necessary to bring about a fatal termination varies in different animals, and in the same animal under

different conditions. It has been noted that the young of some animals resist asphyxia longer than the adults. Paul Bert has shown that these differences are all explicable in accordance with the law that the more active the vital combustion, the greater the gaseous interchange, and therefore the more rapidly fatal the obstruction of the respiratory process. Excluding special considerations of this kind it may be stated as the result of the experiments of the Medical and Surgical Committee on Suspended Animation (*Méd.-Chir. Trans.* vol. xlv. 1862) that when the respiration of a warm-blooded animal is totally obstructed, all external movements cease in from three to five minutes, and the heart stops within ten minutes. Certain modifications occur according to the method in which asphyxia is produced (*see DROWNING*).

ANATOMICAL CHARACTERS.—The blood is of a dark colour, owing to complete reduction of the hæmoglobin, and the proportion of carbonic acid is greatly increased. Owing to the excess of carbonic acid, the blood coagulates slowly or imperfectly; hence it remains long fluid, or forms few and soft coagula. The venous side of the heart, the great venous trunks, and the pulmonary artery are distended with dark blood, while the left side varies, being sometimes full, more often perhaps either empty or containing a small quantity of dark blood.

The appearance of the lungs is not constant. These organs are by no means always congested, as is very generally stated, being more often pale and anæmic. The posterior and dependent parts become hypostatically congested *post mortem*. The abdominal viscera are usually congested. The appearance of the brain varies, this organ being either anæmic or more or less congested. Special signs characterise special modes of causation of asphyxia.

PATHOLOGY.—Inasmuch as the cessation of respiration means both oxygen-starvation and accumulation of carbonic acid, the question is whether the phenomena of asphyxia depend on the one or the other, or on both. Various opinions have been entertained on this subject, but the experiments of Rosenthal and Pflüger would seem to show that the deprivation of oxygen is the chief factor. That the accumulation of carbonic acid has no effect at all cannot, however, be maintained, for it is demonstrable that carbonic acid has a distinct toxic effect on living tissues.

The circulation of non-oxygenated blood through the lungs and the respiratory centre in the medulla oblongata is the cause of the powerful respiratory efforts in the first stage—directly, by stimulation of the respiratory nerve-centres; indirectly, by peripheral irritation of the pulmonary branches of the *vagi*. The respiratory movements increase in force, and the irritation irradiates into the centres of other movements besides those directly concerned in respiration, giving rise to the expiratory convulsions which have been ascribed by some to excitation of a special 'convulsion-centre' (*Krampfcentrum*).

The respiratory centres ultimately become paralysed, but subsequently to those of conscious activity—the brain; and of reflex action—the spinal cord.

The circulation of non oxygenated blood like-

wise causes contraction of the arterioles from irritation of the vaso-motor centre. Increased resistance is thus offered to the heart, and this is intensified by the convulsive muscular efforts. The arterial tension rises. The resistance to the flow through the capillaries by contraction of the minute blood-vessels occurs not only in the systemic, but also in the pulmonary circulation. Hence there is resistance both to the arterial and venous side of the heart. The ventricles become distended, and the heart's action laboured. The heart becomes enfeebled by the circulation of non-oxygenated blood in its walls, the diastolic intervals become longer, until the heart finally stops in a state of diastole, with the right side full, while the left may have succeeded in emptying itself.

TREATMENT.—Resuscitation from pure asphyxia is possible so long as the heart continues to beat. After cessation of the heart's action treatment is unavailing, except in cases of cessation from mere over-distension, in which bleeding from the external jugular vein may be resorted to with success. The chief indication in the treatment of asphyxia is to effect oxygenation of the blood by the introduction of air into the lungs. If the medium by which the patient is surrounded is incapable of supporting respiration, he must be immediately removed, or the atmosphere changed. If the air-passage is obstructed by a foreign body, this must be extruded; if this is impossible, or if the obstruction result from disease, tracheotomy or laryngotomy must be resorted to. Means must be adopted of exciting the respiratory centres or respiratory muscles to action; or if these are paralysed and non-excitable, the natural movements of respiration must be imitated artificially, or air introduced by insufflation.

The respiratory centres, if not absolutely paralysed, may be excited reflexly by stimulation of cutaneous nerves, especially those of the face and thorax. This may be effected by the stimulus of sudden cold, or better by alternate dashing of hot and cold water on the face and chest, or by flicking the skin with a towel. These reflex stimuli are often of themselves sufficient to excite respiratory movements; if not, they are powerful subsidiary aids to artificial respiration. The diaphragm may be stimulated to contraction by galvanisation of the phrenic nerve, one pole being placed on the nerve as it crosses the scalenus anticus at the root of the neck, the other on the epigastrium. Chief reliance, however, is to be placed on the methods of *artificial respiration*, which, after all, are the most simple and the most effectual, and possessed of the pre-eminent advantage of being always available. *See ARTIFICIAL RESPIRATION*.

Air may also be introduced into the lungs directly by properly constructed *insufflation-apparatus*, either by the insertion of a tube within the larynx (an operation requiring dexterity, but without danger if skilfully performed, though there is always risk of rupture of the air-vessels from over-distension); or more easily by the insertion of the tube in one nostril, the other nostril and the mouth being closed (Richardson's apparatus). *Mouth-to-mouth-insufflation* is sometimes of advantage, especially in infants. The operator must close the nostrils of the patient,

and, applying his mouth directly to that of the patient, inflate the lungs by his own expiratory efforts. The tendency to inflation of the stomach is considerably counteracted by backward pressure on the larynx. D. FERRIER.

ASPIRATOR.—SYNON.: Fr. *Aspirateur*.—The operation of Pneumatic Aspiration was introduced into practice by Dieulafoy in 1869. Before this period various instruments had been used under the name of 'suction-trochars,' but to Dieulafoy is due the credit of fully appreciating their value.

DESCRIPTION AND MODE OF EMPLOYMENT.—The aspirator consists of a glass syringe, having at its lower end two openings provided with stop-cocks. When the piston is raised and the cocks are closed a vacuum is created in the syringe, which can be maintained by fixing the piston in the withdrawn position. An india-rubber tube is fitted into each of the two openings, and these must be provided with coils of wire inside to prevent them from collapsing. At the end of one tube is fixed a fine hollow needle. The needle should have only one opening, at the point, and not, as is often seen, another at some distance from it. The instrument is thus used:—A vacuum having been created in the syringe by raising the piston whilst both stop-cocks are closed, the needle is introduced into the part to be operated upon. As soon as the opening of the needle is beneath the skin the stop-cock leading to it must be opened. The vacuum will then extend to the point of the needle, and consequently, if it be gently pushed onwards the moment it encounters fluid, this will jet up into the glass syringe, when its nature may be ascertained. This mode of operating with what Dieulafoy calls the 'previous vacuum' is the essential difference between aspiration and suction. In aspiration it is impossible to pass the needle through a collection of fluid without discovering it; whereas without the 'previous vacuum' in the needle this might readily be done. If the fluid is sufficient in amount to fill the syringe, the stop-cock leading to the needle is to be closed and the other opened, by which the fluid may be discharged. The vacuum may then be re-established, and the operation repeated as often as is necessary. By opening both stop-cocks at once and allowing the discharge tube to hang down, the aspirator may be converted into a syphon. The action of the instrument may also be reversed, and it may be employed for injecting fluids. Other varieties of aspirator are in use besides the one above described. In Weiss's the receiver is a glass bottle, from which the air is exhausted by means of a separate exhausting syringe. The objection to this is that if the needle becomes choked, it cannot be cleared by pushing down the piston and driving some of the fluid back through it. Other kinds of aspirator cannot be converted into syphons, and these are objectionable. Weiss's has the advantage of being less liable to get out of order, as the fluid does not touch the exhausting syringe. The needles employed vary in size. Dieulafoy recommends that they should be about $\frac{1}{16}$, $\frac{1}{8}$, $\frac{1}{4}$, and $\frac{1}{2}$ of an inch in diameter, and calls them Nos. 1, 2, 3, and 4 respectively. The aspirator may also be applied to trochars,

but then its distinctive feature is gone, and it becomes but a 'suction trochar.'

The following rules must always be observed in using the aspirator. 1st. See that the needle is pervious and clean and the syringe in order before using it. It is advisable to wash the needle well in strong carbolic acid solution. 2nd. The needle must be pushed straight on in one direction only. Its course must never be altered while the point is under the skin. If no fluid is found, it may be withdrawn and reinserted. It must be held as steady as possible during the aspiration. 3rd. If the fluid will not flow with the force of the vacuum, it is of no use squeezing and pressing the part. This can only do harm. 4th. Aspiration must cease at once when blood comes in any quantity, especially in abscesses. 5th. Keep up the vacuum during the withdrawal of the needle, lest some of the morbid fluid be left in its track. 6th. If the needle becomes choked, force a little of the fluid back through it in order to clear it.

Uses.—Aspiration is used for purposes of diagnosis and treatment. Dieulafoy asserts that with the No. 1 needle it is possible to search for fluid without danger, whatever may be its sort or its nature, and experience has proved this to be practically true. In treatment it has been employed in the following affections:—

Abscesses.—In acute abscesses aspiration is usually of little value, as the pus soon re-accumulates. In chronic abscess connected with diseased bone it usually fails, and often it is impossible, from the amount of cheesy matter in the pus. In chronic abscesses unconnected with bone it sometimes effects a complete cure after three or four repetitions. It has proved successful in curing perinephritic abscess in the writer's experience. It is always well in chronic abscesses of doubtful origin to give this mode of treatment a trial. It must be remembered in treating large chronic abscesses that a dirty needle may lead to decomposition of their contents. **Diseases of the Liver.**—Hydatid cysts have been successfully treated by aspiration. In many cases the fluid becomes purulent after one or two aspirations, and in some the cyst has opened externally. For purposes of diagnosis the small needles may always safely be thrust into the liver. Abscess of the liver has been successfully treated by the aspirator.

Retention of Urine may always be safely relieved by using No. 2 needle above the pubes. **Ovarian cysts** may be diagnosed and treated in the same way. **Hernia.**—It has been asserted that strangulated hernia may be, in the great majority of cases, relieved by the use of the aspirator. The finest needles only should be used. They remove first the fluid from the sac, after which some gas may be obtained from the strangulated gut, but fecal matter rarely fails to choke the tube. In this country surgeons have not succeeded in sufficiently emptying the gut to allow of its reduction. Experience has, however, shown that if the needle be kept steady, any number of punctures may be safely made into the gut. **Diseases of Joints.**—Aspiration is occasionally useful in acute synovitis. Great care must be taken not to scratch the inside of the joint with the needle, as this has been known to lead to acute arthritis and suppuration. No. 1 or 2 needle

should be used. *Hydrocephalus* and *Spina bifida* may be aspirated with safety with No. 1 needle. In *hydrocephalus* it is to be passed through the anterior fontanelle. No case has hitherto been cured by this treatment. In *Pleurisy* and *Abscess*, except for purposes of diagnosis, in the writer's opinion the aspirator presents no advantages over a treacher properly constructed so as to exclude air (see PARACENTESIS). *Pericarditis*.—The operation of aspiration has frequently been successfully performed for pericardial effusion. It is thus carried out:—A spot is chosen 2 to 2½ in. (5 or 6 centimetres) beyond the left edge of the sternum, in the 4th or 5th interspace. No. 2 needle is then passed obliquely upwards and inwards, taking care to turn on the vacuum as soon as the eye is covered. The moment the fluid jets into the syringe the needle must be held steadily till the flow ceases. If this be done there is no danger of wounding the heart. If there is any doubt as to the existence of fluid, No. 1 needle must be employed, with which the heart may be punctured without great danger.

MARCUS BECK.

ASTHENIA } (ἀ, priv., and σθέος, strength). ASTHENIC }

—Terms signifying want of strength. As applied to the entire system, they indicate considerable general debility; in connexion with particular diseases, they imply that these are attended with marked weakness.

ASTHENOPIA (ἀ, priv., σθέος, strength, and ὤψ, the eye)—Weakness of sight. See VISION, Disorders of.

ASTHMA, SPASMODIC (ἀσθμα, from ἄω, I blow).—SYNON.: Bronchial Asthma. Fr. *Asthme*; Ger. *Bronchial-Asthma*.

DEFINITION.—An affection characterised by severe paroxysmal dyspnoea, recurring at more or less well-marked periods, generally in the night, the dyspnoea being due to spasmodic contraction of the bronchi, produced by a variety of causes.

ÆTIOLOGY.—The causes that induce an attack of asthma are very various, and may be roughly classed according to their action, *direct* or *indirect*, on the respiratory organs. In the former the exciting cause immediately affects the mucous membrane, in the latter it does so in a more circuitous manner, as through the blood or the nervous system generally:—

Direct	Dust.	Indirect	Through the nervous system .	{	Centric.
	Vegetable irritants.				
	Chemical vapours.				
	Animal emanations.				
	Climatic influences.				
	Bronchial inflammation.	Through the blood	{	Excito-motor.	Gout.
		Heredity.	{	Skin diseases.	Ronal diseases.

Direct causes.—Common roadside dust; stuff from woollen clothing; the dust of mills, threshing-floors, or bakehouses; and any mechanical particles when inspired, will produce in some persons an asthmatic seizure, dust of low specific gravity being more apt to have this effect than heavy

particles like coal, steel filings, etc., from which arise lesions in the lung of a more permanent and serious character.

The odour evolved by certain vegetables, such as ipecacuanha; the pollen of many grasses and plants (see HAY-FEVER); certain chemical vapours, as that of pitch, sulphurous acid, and phosphorus fumes; the peculiar smell of some animals, as dogs, cats, horses, and hares, may each provoke a spasm in individual cases.

A still more powerful cause is climatic influence, the action of which on different patients cannot, unfortunately, be reduced within the limits of law, but depends mainly on the idiosyncrasy of the individual. Extremes of temperature, or excessive dryness or dampness, may produce an asthmatic seizure, but in the largest number of cases one of two elements appears as the chief factor. One large class of sufferers trace the attack to *dampness*, whether of soil or of atmosphere, in combination with either heat or cold, another to *cleanness* of atmosphere and a want of proper circulation of air, such as is found in deep valleys and thick forests, and during thundery weather—this last class experiencing great relief when a breeze springs up. Malaria plays an important part occasionally in the causation of asthma.

Far more general and intelligible in its action is bronchial inflammation, which is the cause in 80 per cent of asthmatic cases. It frequently happens that after whooping cough, measles, or infantile bronchitis the tendency towards asthma begins to appear. These diseases, implicating as they do both bronchial muscle and nerve supplying it, leave their mark behind, either in irritability of the mucous membrane; in induration of some portion of the lung, generally at the root; or in enlargement of the bronchial glands, causing pressure on the pneumogastrics, or on some of the branches of the pulmonary plexuses (see BRONCHIAL GLANDS, Diseases of); and thus we often find that the diseases which implicate the bronchial tubes in childhood lay the foundation of asthma in after-life.

Indirect causes.—This class of causes includes those acting through the general nervous system; those acting through the blood; as well as the more or less structural ones of heredity.

The *centric* subdivision embraces attacks arising from emotion, anger, or fright; as well as the curious alternations of asthma, neuralgia, angina, and gastralgia due to some centric irritation in the medulla, involving the origins of the fifth and eighth pairs of nerves, and manifesting itself by affecting first one branch and then another of these nerves.

Excito-motor causes may be illustrated by indigestion or costive bowels giving rise to a paroxysm of asthma. In the first case, irritation of the medulla is induced through the gastric branches of the pneumogastric, and a motor effect is reflected through the pulmonary branches. These *peptic* attacks, as they are called, occur more frequently after suppers than dinners, probably because reflex irritability is always exalted by sleep, as we know to be the case in epilepsy and the teething convulsions of childhood.

Gout, towards old age, often takes the form of asthmatic seizures, which alternate with the

articular affections. In like manner attacks of the disease have been attributed to syphilis.

The connexion between asthma and various kinds of skin-disease is intimate; the subsidence of eczema, of urticaria, or of psoriasis, has often been accompanied by fits of spasmodic breathing, which have ceased on the reappearance of the eruptions. Here, again, the state of the blood is presumed to be the origin of both maladies, as in disease of the kidneys, which will be again referred to.

Heredity can be traced in about 40 per cent. of asthmatics, though the tendency often does not show itself till late in life. The characteristic form of chest is often transmitted from parents to children; and even when this is not so, a disposition towards spasmodic symptoms in catarrhal attacks is often seen in the children of some asthmatics.

SYMPTOMS.—The patient retires to bed with few or no premonitory symptoms, and sleeps for some hours, but is disturbed in the late night or early morning—two A.M. is a common time—by a feeling of oppression approaching to suffocation, referred either to the throat, sternum, or epigastrium, which obliges him to sit up in order to breathe. Sometimes the onset is more gradual; the patient, having fallen asleep in spite of uneasy sensations, begins to wheeze during sleep, and is only aroused when the dyspnoea becomes severe. The breathing is accompanied by a humming sound, which gradually develops into a great variety of discordant noises.

In order to increase the capacity of his chest to the utmost, the asthmatic patient sits up and fixes his shoulders, either by placing his hands on either side of him, or by supporting his elbows by his knees; or sometimes he stands leaning over the back of a chair or other support. In one or other of these positions he remains immovable, with chest, back, shoulders, and head fixed; unable to speak or even to move his head; the lips being parted; the face pale, anxious, and, if the dyspnoea continue, livid; and the eyes prominent and watery. Every muscle of respiration, ordinary and extraordinary, is brought into requisition; those passing from the head to the shoulders, to the clavicles, and to the ribs become rigid, and, in place of moving the head and neck, act the reverse way, being used as fixed points to raise and dilate the thorax. The trapezii and levatores anguli scapulae by their contraction elevate the shoulders, in order that the muscles connecting these with the ribs may act as elevators to the latter. Even the muscles of the back are pressed into the service, and they almost cease to support the back; consequently the patient stoops. At each inspiration the sterno-cleido-mastoids stand out like cords, leaving a deep hollow between their sternal attachments; the diaphragm is contracted, and hence the stomach, liver, and heart are somewhat displaced. With all this display of muscular force, the chest remains almost motionless, being expanded to a variable extent.

In spite of the great dyspnoea, respirations are not proportionately frequent, seldom exceeding thirty, and sometimes falling to nine a minute. The expiration is prolonged, being generally two or three times as long as the inspiration. The

pulse is usually slow and feeble; the temperature rarely exceeds 99° Fahr., and is often below 98° Fahr. Analysis of the expired air shows the oxygen to be almost entirely replaced by carbonic acid, which may increase from the normal to as much as 11 per cent., the nitrogen varying from 89 to 93 per cent. The arrest of expiration is probably the cause of the accumulated carbonic acid, but the total disappearance of the oxygen is hardly to be explained, for that oxidation of the tissues does not proceed, is shown by the pale urine passed after the fit.

PHYSICAL SIGNS.—These reveal less than might be expected. The percussion-note is somewhat raised over the whole chest, most so in the posterior regions, where a drum-like sound occasionally prevails: this hyper-resonance is probably due to accumulation of air induced by obstructed expiration, and in incipient cases passes off with the attack.

Auscultation shows an entire abolition of the normal breath-sounds, and the existence of dry sibilant or sonorous rhonchi, every where varying in tone according to the calibre of the bronchial tubes; the smaller ones giving the high notes, and the larger ones the deep notes. These sounds continually change their position, springing up under the listening ear, and as quickly vanishing again to give place to profound silence.

PROGRESS AND DURATION.—A paroxysm of asthma, when once established, lasts from half an hour to several days, and generally terminates with expectoration—thin and transparent if the seizure be short; but abundant and more or less opaque if the fit be prolonged, or if the case be chronic. The urine is light-coloured and plentiful; and flatus is often expelled from the bowels. Little or no food is taken during the attack, at the close of which the patient falls asleep.

The recurrence of the attacks when once they have been excited is generally periodic, but much depends on the presence or absence of the exciting cause. In many cases the patient is quite free from wheezing and dyspnoea in the intervals, and feels and acts like other people; but when the attacks follow each other closely, a more or less wheezy condition remains behind, and a few signs of obstructed breathing are generally to be detected in the interscapular regions.

COMPLICATIONS AND SEQUELÆ.—If the asthmatic attacks become habitual, their effects are seen on the frame and on the organs implicated. The shoulders become raised, the head being buried between them; the muscles of the back, owing to their being called on to act as extraordinary muscles of respiration, are diverted from their use as erectors of the spine, which, accordingly, yields in the anterior direction, and the patient stoops. The frequent occurrence of spasmodic contraction of the bronchi causes hypertrophy of their muscular coat; and this, with or without the congestion of the mucous membrane accompanying it, leads in time to thickening of the tubes and permanent narrowing of their calibres. The more common result of asthma is emphysema, arising from the difficulty of expiration. The emphysema, at first temporary, becomes in chronic cases permanent, and gives rise to displacement of the adjoining organs (*see Emphysema*).

asma). Contraction of the bronchia largely influences the pulmonary vessels, and considerable obstruction of the pulmonary circulation is the result. The vessels become gorged, and sometimes the lungs oedematous. If the emphysema be extensive, we may in time expect dilatation of the right side of the heart and marked prominence of the veins of the breast and neck, and the effects may be carried so far as to cause oedema of the lower extremities with albuminous urine, as the writer witnessed in a case where the latter symptoms disappeared on the subsidence of the asthma.

PATHOLOGY.—Patients rarely, if ever, die of spasmodic asthma, though death may ensue from some of its complications and sequelæ; and the disease being a functional one, cannot be said to have any morbid anatomy. The onset and departure of the attack, and the ever-changing physical signs, led Laennec to think that, whatever obstruction in the bronchial tubes caused the phenomena, must be of a spasmodic and transitory nature. He therefore concluded that asthma was due to a spasm of the bronchial muscles which had been described by Reissowien. Laennec also showed that an asthmatic sufferer could sometimes, after holding his breath, actually breathe naturally for one or two respirations, thus clearly demonstrating that the spasm was capable of momentary relaxation. Other theories were put forward, and doubt was thrown on the existence of muscular fibres in the bronchi, until Dr. C. J. B. Williams proved their existence by his experiments on the lungs of oxen, dogs, rabbits, and other animals, when he caused contraction of the trachea and bronchial tubes by the application of electrical, chemical, and mechanical stimuli. The muscular coat was shown to be more abundant in the smaller tubes than in the larger, the former contracting sufficiently to entirely obliterate their passages. In asthma, excitation of the muscle probably takes place through the anterior and posterior pulmonary plexus, which are made up of branches from the pneumogastrics, recurrent laryngeals, the spinal nerves, and the ganglia of the sympathetic, thus giving the bronchial tubes a very wide area of connections. The branches of the pulmonary plexus form a network round the bronchial tubes, and contain some minute ganglia. When the cause is direct, as dust of any kind or climatic influence, the spasm may be induced by reflex action through these small ganglia, or through the pulmonary plexus, though it soon extends deeper into the nervous system, involving the pneumogastrics and causing a motor effect on the thoracic muscles through the upper cervical, phrenic, and dorsal nerves. Where emotion, fright, or laughter starts the fit, the irritation is centric, and causes a motor effect on the pulmonary plexus through the pneumogastrics. Where, again, indigestion excites it, the sensation passes through the gastric branches of the pneumogastric, and is reflected by the motor filaments of the pulmonary plexus. Lastly, where gout, syphilis, skin-disease, and heredity are the excitants, we may regard the blood itself as causing the local irritation. Spasmodic asthma may, therefore, be considered as a nervous of the pul-

monary branches of the plexus of that name similar to other nervous, as hemicrania and sciatica, and giving rise through the motor nerves of the plexus to spasm of the bronchial muscle.

DIAGNOSIS.—Asthma is distinguished from *bronchitis* by the fugitive physical signs; by the spasmodic character of the dyspnoea; and by the scant expectoration. The breathing in bronchitis, if at all difficult, is hurried; if asthma it is slow, wheezy, and prolonged; this feature also contrasting strongly with the gasping, panting dyspnoea generally accompanying pneumonia, pleurisy, and some forms of heart-disease. From *croup* it is recognised partly, but not entirely, by the age of the patient; and partly by the character of the dyspnoea, which in croup is *inspiratory*, whereas in asthma it is mainly *expiratory*. This characteristic also distinguishes asthma from *spasm of the glottis* and the various forms of *laryngeal dyspnoea*. The diagnosis from *emphysema*, which is so often mixed up with spasmodic asthma, is founded chiefly on the paroxysmal character and violence of the asthmatic dyspnoea; and on the complete freedom of the intervals, the dyspnoea of emphysema being more or less permanent.

Aneurism of the aorta and other *mediastinal tumours* often give rise to symptoms so exactly simulating spasmodic asthma as to make the diagnosis difficult, and this is to be accounted for by these tumours pressing on the pneumogastric and its branches, and thus inducing an asthmatic spasm. These cases are, as a rule, however, accompanied by a certain amount of stridor arising from laryngeal spasm, not present in asthma, and this symptom is often of great diagnostic value in obscure cases. As the tumour enlarges, it causes greater pressure on the lungs, trachea, œsophagus, sympathetic ganglia, or other structures, and produces shrill cough, dysphagia, difficulty of inspiration, pain in the chest, impulse in the thoracic wall and other noted aneurismal symptoms. Moreover, certain physical signs become evident, *e.g.* dulness over the first portion of sternum or to the right of it, or between the scapulae; tubular sounds and bronchophony close to the sternum, or above one or both scapulae; or some form of bruit or murmur in the course of the aorta. These and other symptoms and signs contrast sufficiently with those of spasmodic asthma, to make the diagnosis from developed aneurism comparatively easy.

In some cases of *renal disease* a form of dyspnoea appears, which is occasionally marked by paroxysmal features, and has been mistaken for spasmodic asthma. Renal dyspnoea differs, however, as a rule, in being more continuous, and in having for its origin oedema of the lung rather than bronchial spasm.

PROGNOSIS.—The question of recovery in cases of asthma depends to a certain extent,—

Firstly, on the possibility of the removal of the exciting cause;

Secondly, on the age of the patient;

Thirdly, on whether the attacks increase or not in frequency;

Fourthly, on the condition of the lungs and breathing in the intervals.

If the patient be young (say, under fifteen), the

chest well-formed, the attacks tending to diminish in frequency and intensity, and the lungs free in the intervals, a most hopeful prognosis can be given. If, on the other hand, the patient be middle-aged, the attacks increasing in number and severity, and the breath more or less short in the intervals, we may conclude that there exists a considerable amount of permanent emphysema, which renders the prognosis of an unfavourable character. In every instance the detection and removal of the exciting cause or causes, as the case may be, exercise a chief influence over the prognosis.

TREATMENT.—The principal difficulty in the treatment of asthma lies in clearly ascertaining the origin of the irritation, and when this is discovered two great principles should guide us, namely, first, to avoid or remove the exciting cause; secondly, to allay and prevent the spasm.

Many of the cases arising from direct causes, as from dust, chemical vapours, &c., are cured by simple avoidance of the exciting cause. Where bronchial inflammation induces the spasm, the inflammation must be subdued by salines and expectorants, combined with some anti-spasmodic, as belladonna, henbane, or stramonium. In more chronic instances, where some thickening of the walls of the larger bronchi and enlargement of the bronchial glands exist, iodide of potassium in doses of grs. iii. to x., has been found beneficial when persisted in for long periods. Where the attacks depend on a morbid state of blood, as that associated with gunt, syphilis, renal disease, or connected with skin-disease treatment must be directed to the condition of this fluid, which, if improved, will no longer induce bronchial spasm. Arsenic proves of signal service in asthma co-existing with eczema, psoriasis, and other skin-affections.

Where heredity is the predisposing cause, the origin of the disease lies generally in defective development of the frame or of the lung-structure of the patient: for such persons gymnastic exercises, swinging on the trapeze, and other means of expanding the upper part of the chest and correcting the asthmatic stoop are to be employed, combined with cold sponging and as much outdoor life as possible, with walking and riding in moderation. The tendency to catarrh is thus lessened, and the frame of the patient developed and fortified. In a large number of cases, as, for instance, those arising from climatic influences, we have to treat a simple neurosis, and to allay the spasm either by climatic or by medicinal means, of which the former is often the more important, and, owing to the leading part played by the idiosyncrasy of the patient, generally the most difficult. In obstinate cases the doctrine of contrasts appears the only safe one. Where the disease has been contracted in a moist climate, a dry one must be tried; if in an inland district, the seaside must be resorted to; but for by far the majority of asthmatics the atmosphere of large towns is suitable, and the smokier the air and the closer the streets the more good do the sufferers appear to receive. London, Glasgow, Birmingham, and Bristol are all favourable resorts for cases of neurotic asthma: and the points of difference

between their atmospheres and that of the country consist, (1) in dryness; (2) in deficiency of oxygen; and (3) in excess of carbonic acid and carbon: all of which peculiarities appear to exercise a sedative effect on the neurosis. Damp, whether of soil or atmosphere, is usually found to be hurtful, and is one of the chief exciting causes of asthma.

The medicines most useful in asthma are anti-spasmodics, either stimulant or sedative: the former, including alcohol, strong coffee, spiritus ætheris, and nitrite of amyl, will prove more efficacious where emphysema is present; the latter comprise stramonium, belladonna, Indian hemp, lobelia, tatula, tobacco, opium with its salts, and many other drugs. These may be taken internally in the form of extracts or tinctures; or smoked in pipes or as cigarettes; or inhaled as vapour diffused through the room by burning papers or pastilles containing them. A popular and often reliable remedy is the vapour arising from the combustion of nitre-paper. In the severest attacks the patient can neither smoke nor swallow, and in this difficulty of introducing medicines into his system we find the hypodermic injection of atropine, morphia, and chloral proves effectual; but if emphysema be present, or if the pulse be weak, it must not be attempted. Chloroform often acts like a charm in the worst case, and after inhaling 20 to 60 minims the patient will gain the sleep which has been denied to him for hours, or even days; but the effect is generally transitory, and the use of the remedy not free from risk. Ether is safer, but not so effective. Chloral-hydrate in doses of 15 to 20 grs., repeated every four hours until the spasm subsides, has produced not only temporary, but even permanent good in a large number of asthmatic cases, and if watched, may be persisted in for some time. In the writer's hands it has proved the most successful remedy. In the use of anti-spasmodics we must avoid judging the effects of one from the failure of another of the same class; but in difficult cases we must try each in succession—for it often happens that the successful remedy is only arrived at after repeated trials.

Certain mineral waters, and especially those of Mont Dore and the Pyrenean sulphur springs of Eaux Bonnes, Eaux Chaudes and Cauterets, are reputed to exercise a beneficial influence over asthma, but they have not been successful in the writer's experience, and it is more probable that they relieve by reducing the catarrhal symptoms than that they either allay the spasm or prevent its recurrence.

Compressed air baths at pressures varying from 3½ to 7 inches of mercury, and lasting two hours, have afforded considerable relief. See AIR, Therapeutics of.

The dietetic treatment varies in individual cases, but as a rule asthmatics should dine early, and for the rest of the day limit themselves to liquid food, such as beef-tea, soups, and milk, combined with such an amount of stimulant as may be necessary, thus avoiding any distension of the stomach and intestines before retiring to rest. The diet should consist of brown bread, toast, and biscuits—excess of starch in any form being studiously avoided—a fair supply of plainly

cooked meat, fish or poultry, and a limited amount of vegetables and fruit, care being taken to select only the most digestible of each class.

C. THEODORE WILLIAMS.

ASTIGMATISM — ASTIGMISM (ἀ, priv., and *stigma*, a spot or point).—Want of symmetry in the anterior refracting surfaces of the eyeball, in consequence of which rays of light proceeding from a point cannot be brought to a focus upon the retina as a point, but only as a diffused spot. See Vision, Disorders of.

ASTRINGENTS. — DEFINITION. — Medicines which cause the contraction of tissues.

ENUMERATION.—The chief astringents are Nitrate of Silver; Sulphate of Copper; Sulphate of Zinc; Acetate of Lead; Perchloride of Iron; Alum; Tannic and Gallic acids, and vegetable substances containing them, such as Oak Bark, Galls, Kino, and Catechu; and Dilute Mineral Acids. Some authors also include in this class of remedial agents such articles as Ergot of Rye, which contracts the blood-vessels and lessens hæmorrhage after it has been absorbed into the blood, although it has no local astringent action.

ACTION.—With the exception of gallic acid, the substances already mentioned coagulate or precipitate albumin. Dilute mineral acids do not coagulate albumin, but precipitate many albuminous bodies from the alkaline fluids by which they are held in solution. When applied to a surface from which the epidermis has been removed, the other astringents combine with the albuminous juices which moisten this surface, as well as with the tissues themselves, and form a pellicle more or less thick and dense, which in some measure protects the structures beneath it from external irritation, at the same time that they cause the structures themselves to become smaller and more dense. On a mucous membrane they have a similar action, and they lessen its secretion. It was formerly supposed that their action was partly due to their causing the blood-vessels going to a part of the body to contract, thus lessening the supply of fluid to it; as well as to their effect on the tissues themselves. But experiment has shown that, while nitrate of silver and acetate of lead possess this power, perchloride of iron and alum do not, and that tannic and gallic acids actually dilate the vessels. The astringent action of these latter drugs must therefore be exerted upon the tissues.

Uses.—Astringents may be employed locally in various forms. In the solid form, as a powder, or in various preparations such as lotions, ointments, plasters, glycerines, &c., they are applied, especially the metallic astringents, to wounds and ulcers for the purpose of reducing the size and increasing the firmness of exuberant granulations, as well as of protecting the surface by forming a pellicle over it. They are used to lessen congestion and diminish the secretion of the various mucous membranes—as a lotion to the eye and mouth; as a gargle or a spray to the throat; in the form of an injection to the nose, urethra, and vagina; and as a suppository to the rectum. Administered internally several astringents have a powerful effect in checking diarrhoea, and certain of them

may have a local action upon the stomach and intestines.

The remote action of such astringents as acetate of lead and gallic acid, when absorbed into the blood, in lessening hæmorrhage, is made available in the treatment of hæmoptysis, hæmatemesis, hæmaturia, and loss of blood from other parts of the body.

T. LAUDER BRUNTON.

ASTURIAN ROSE.—The rose or crythema of the Asturias; one of the numerous synonyms of Pellagra—*Mal de la rosa*; *Lepra Asturiensis*; *Elephantiasis Asturica*. See PELLAGRA.

ATAVISM (*atarus*, a grandfather) signifies the inheritance of a disease or constitutional peculiarity from a generation antecedent to that immediately preceding.

ATAXIA } (ἀ, priv., and *taxis*, order). —
ATAXIO }

Terms which originally meant any irregularity or disorder, but are now specially applied to irregularity of associated or co-ordinated muscular movements. The noun is frequently used as synonymous with the disease known as Locomotor Ataxy. See LOCOMOTOR ATAXY.

ATELECTASIS (*ἀτελής*, imperfect, and *έκτασις*, expansion).—Absence or imperfection of the expansion of the pulmonary alveoli which normally takes place at birth, the lungs thus remaining more or less in their fetal condition. See LUNGS, Collapse of.

ATHEROMA. See ARTERIES, Diseases of.

ATHETOSIS (*ἄθετος*, without fixed position).—DEFINITION.—A name given by Dr. Hammond of New York to a condition in which the hand and foot are in continual slow irregular movement, and cannot be retained in any position in which they may be placed.

DESCRIPTION.—The special character of the movements in athetosis is that they are slow and deliberate. They usually affect the arm and leg on one side only. Voluntary power is retained, but is interfered with by the slow spasm. The fingers are irregularly flexed and extended: at one moment they spread wide apart, the thumb being over-stretched, thereafter first one, then another is bent in to the palm, and again extended. The movement can be arrested for a moment in certain positions by the will, but is renewed with increased force. The foot is usually inverted; the toes being flexed or extended, but in less constant movement. The spasm may cause pain. The muscles sometimes become hypertrophied. The movements in some cases cease during sleep, in others they do not. Sensation is often, but not always impaired. The onset of this condition is usually sudden, and in some cases with a convulsion. The subjects have been generally in middle life.

Athetosis differs from the spastic contracture so common after hemiplegia in children in the slowness and spontaneity of the movements; but the two conditions are probably very closely allied. It cannot be regarded as a distinct disease. Typical athetosis may succeed hemiplegia.

PATHOLOGY.—It is probable that, as Dr

Hammond suggests, the seat of the mischief in athetosis is the corpus striatum or optic thalamus. The sudden onset of the disease, and the slight affection of sensation, render it probable that a lesion damaging, but not destroying, a portion of one of these nuclei, leads to a perverted action of the nerve-cells, so that abnormal motor impulses are originated, and those transmitted from above disturbed—'irradiated' (Nothnagel). Charcot believes that all post-hemiplegic choreoid movements depend on the implication of fibres outside the optic thalamus. In a case of simple ataxy after hemiplegia—an analogous condition,—the writer has found a cicatricial sclerosis extending across the optic thalamus, and probably left by a patch of softening.

PROGNOSIS.—This is unfavourable, but the slighter cases improve and may even approximately recover.

TREATMENT.—Nervine tonics and sedatives are the remedies chiefly indicated. Of the former arsenic, and of the latter Indian hemp, do most good; bromides are also useful. The continuous current is perhaps the agent which affords most distinct relief. In one well-marked case under the writer's care the spontaneous movements ceased entirely after some months' galvanisation. The positive pole may be placed on the spine or brachial plexus, the negative on the muscles involved. The action of the continuous current is probably in part direct, in part reflex, lessening by the peripheral impression the over-action of the centre, as do some other peripheral impressions.

W. R. GOWERS.

ATONIC } (à, priv., and *réros*, tone).— ATONY }

Terms implying want of tone, power, or vigour, and associated either with such a condition of the system generally, or of particular organs, especially those which are contractile.

ATRESIA (à, priv., and *trénu*, I pierce).—Absence of a natural opening or passage, whether congenital or caused by disease.

ATROPHY, GENERAL.—**SYNON.**: **Marasmus.**

DEFINITION.—Atrophy means, etymologically, simply want of nourishment (à, priv., and *τροφή*, nourishment), but the term is commonly applied to the condition resulting from want of nourishment, namely, wasting or diminution in bulk and substance, even though this may have been produced by some other cause, and even though the supply of nutritive material may have been abundant. *General atrophy* is used to denote wasting in which the whole body participates. All acute diseases, if severe, are accompanied by emaciation, for at such times nutrition is temporarily interfered with. The use of the word 'atrophy' is, however, confined, as a rule, to cases where the interference with nutrition has been gradual, and the loss of flesh consequently slow.

ETIOLOGY.—Atrophy is common enough at all periods of life. In infants and children it is due, in the majority of cases, to chronic functional derangements which interfere with the digestion and elaboration of food. Less frequently it is a

consequence of organic disease. In adults general atrophy seldom results from any other cause than organic disease, and functional disorder as a cause of serious wasting is the exception. In old age atrophy is a common consequence of the degenerations of tissue which accompany the decline of life. The interference with nutrition may, however, be aggravated by the presence of disease.

In *infants under twelve months old* there are four principal causes to which chronic wasting can usually be referred, namely, unsuitable food, chronic vomiting (gastric catarrh); chronic diarrhoea (intestinal catarrh); and inherited syphilis. Bad feeding, by setting up a chronic catarrhal condition of the stomach and bowels, is a frequent cause of both vomiting and diarrhoea, but it may produce atrophy without either of these symptoms. When an infant is fed, for instance, with large quantities of farinaceous matter—a form of food which is alike indigestible and innutritious—a very small part only can enter as nutriment into the system. The remainder passes down the alimentary canal, and is ejected at rare intervals in an offensive putty-like mass or in hard roundish lumps. The child, therefore, although overloaded with food, is really under-nourished, and loses flesh as long as such a diet is persisted in. If, as often happens, diarrhoea or vomiting be set up by the irritation to which the digestive organs are subjected, wasting is more rapid and the danger of the case is increased. Any form of bad feeding, and not only excess of farinaceous matter, will produce this result. Wasting, indeed, will be found in every case where the food selected is unfitted for the child, and thus it is not infrequently seen in infants who are fed upon milk and water alone. The casein of cow's milk is difficult of digestion by many infants on account of its tendency to coagulate into a large firm clot like a lump of cheese. In this respect it differs from the curd of human milk, which forms light small flocculent coagula, and is digested without difficulty. Special preparation is therefore generally required to render cow's milk a suitable diet for a young child.

It is not only, however, unsuitable food which is a cause of atrophy in infants. Catarrh of the stomach and bowels may be present, although the feeding is in all respects satisfactory. Infants are excessively sensitive to chills, and catarrh of their delicate digestive organs is easily excited. Now, catarrh of a mucous membrane is always accompanied by an increased flow of mucus, and this alkaline secretion in excess acts as a ferment and sets up decomposition of food. A sub-acute gastric catarrh from this cause is not rarely seen in new-born infants, who thus are rendered for the time incapable of digesting even their mother's milk. In such cases the fault is usually attributed to the milk, which is said to be unsuited to the child; and the mother is compelled, much against her will, to wean her baby and feed it in a different way. So long as the catarrh continues, however, no food appears to agree, and the child often after a time dies exhausted.

Between one and three years atrophy is commonly associated with rickets. In these cases,

the wasting is noted chiefly about the chest and limbs, for the belly is large and swollen from stercoral accumulation. At this age children are still liable to waste from catarrh of the stomach and bowels: indeed, rickets is itself often complicated by such derangements. Cancer of the internal organs is also sometimes found at this time of life, and is attended with extreme emaciation.

After the age of three years caseous enlargement of the mesenteric glands becomes a cause of wasting.

After the fifth or sixth year chronic pulmonary phthisis begins to appear. Cases of heart-disease as a result of acute rheumatism are also more frequently seen. Diabetes, too, is sometimes met with. All these diseases may produce much interference with nutrition.

From the time that the child begins to take other food than that furnished by his mother's breast, he is liable to worms in the alimentary canal. The presence of worms is frequently accompanied by loss of flesh, not, perhaps, so much on account of the parasites themselves, as on account of the derangement of the digestive organs which is associated with them. Emaciation due to this cause may sometimes be extreme.

In the adult atrophy is rarely the result of mere functional derangement, but is almost invariably a sign of serious organic disease. All chronic ailments are not, however, accompanied by marked wasting. Purely local diseases lead to little loss of flesh unless they affect some part of the digestive apparatus, or of the glandular system which is concerned in the elaboration of nutritive material; or otherwise directly influence the processes of nutrition. Thus, emaciation quickly results from gastric ulcer or chronic dysentery, but chronic pneumonic phthisis may produce little diminution in weight if there is no pyrexia, and if the case is not complicated by diarrhoea or profuse expectoration. The most marked atrophy is produced by the so-called constitutional diseases, such as cancer and syphilis in the third stage, by those which set up a persistent drain upon the system, such as severe albuminuria, chronic hæmorrhages, and long-continued suppurations; or by those which directly impede the passage of nutritive material into the blood: and in the latter class of diseases, influences which act directly upon the thoracic duct, such as obstruction to its passage from pressure by aneurism and other tumours, must not be overlooked. There is a form of atrophy sometimes seen in hysterical females, depending upon disordered innervation, in which the most extreme emaciation may be reached. Such cases are marked by a dislike to food which may amount to absolute loathing.

SYMPTOMS.—The symptoms of general atrophy are loss of flesh, loss of colour, and loss of strength, combined with other special phenomena arising from the particular disorder to which the impairment of nutrition is due.

ANATOMICAL CHARACTERS.—The most marked post-mortem appearance in this condition is diminution or loss of fat, especially of the subcutaneous adipose tissue; and this is accompanied by wasting of the tissues and organs

generally. The histological elements are reduced in size without undergoing, as a rule, actual numerical diminution. With the atrophy is often associated a certain amount of fatty degeneration.

TREATMENT.—The treatment of general atrophy consists in removing, if possible, the impediment to efficient nutrition. In the case of a child the diet must be selected with care. Excess of farinaceous food is to be avoided, and cow's milk can be diluted, if necessary, by admixture with thin barley water. Any gastric or intestinal derangement must be at once remedied, plenty of fresh air should be obtained, and perfect cleanliness strictly enjoined. In an adult the disease which is the cause of the malnutrition must be sought for and submitted to treatment. Efforts should be made on the one hand to arrest any drain upon the system, and, on the other hand, by a judicious arrangement of the dietary, and by attention to the eliminatory organs, to remove all obstacles to the entrance of nourishment. Even in cases of organic and incurable disease much benefit may often be derived from due observance of physiological laws.

EUSTACE SMITH.

ATROPHY, LOCAL.—This condition signifies atrophy of a part of the body, which may be apparently congenital, or may be produced by various causes acting during life. It will be convenient to consider local atrophy according to the several forms which are met with.

Congenital Atrophy is that condition in which some part of the body never reaches its full standard of size. It is more correctly denominated *arrested growth* or *congenital smallness*. When the whole of one side of the body is thus affected, a marked and permanent disproportion between the two sides results. This *hemiatrophy* is, in theory, difficult to distinguish from hypertrophy of the opposite side, but mostly the paralytic or enfeebled state of the atrophic side shows it to be abnormal. The limbs are most strikingly implicated, while the corresponding side of the face and head is sometimes similarly, sometimes conversely affected. In many cases atrophy of the opposite half of the cerebrum was found on post-mortem examination. The same condition may be partial—*hemiatrophia partialis*—and it then chiefly affects the face, or some part of the territory of the fifth cranial nerve. These conditions must be ascribed to some perversion of innervation occurring during development. Other congenital atrophies, *local* but not *hemis*-atrophic, are more probably referred to obstruction of blood-vessels during the same process. The defective development of the brain in cretinism has been attributed to the pressure of an enlarged thyroid upon the carotid arteries.

Physiological Atrophies.—These form a distinct class, where atrophy of a part of the body takes place in the ordinary course of development. Such are the wasting of the thymus gland in early life, of the mammae and sexual organs after middle age. Most commonly the atrophy is here closely connected either with the involution or perhaps the development of some correlated organ; but it is not possible

to say what the nature of this connection is, whether one of nutrition or of innervation.

Acquired Atrophies.—The conditions thus distinguished possess most interest for the practical physician. Wasting of any part of the body during life, when not physiological, usually depends either upon some interference with the blood-supply, or some disturbance of innervation; but to those must be added, in the case of organs which have an active and continuous function, disuse or over-stimulation. Deficient blood-supply, which causes atrophy, may be produced by the obstruction of a nutrient artery, especially if it be gradual, since sudden blocking will produce more complicated phenomena. Constant pressure is a cause of atrophy, because it interferes both with the blood supply, and with the vital actions of the tissue-elements. Intermittent pressure, on the other hand, by causing hyperæmia, is more likely to lead to hypertrophy. Moreover, inadequate renewal of blood, that is, filling of the vessels, even to excess, with venous blood, or venous engorgement, though at first it may cause enlargement, mostly leads to atrophy in the end; as is seen in the granular induration of liver and kidneys caused by disease of the heart obstructing the circulation. Many forms of atrophy in old age are clearly dependent upon senile obstruction of the arteries, for example, that of the skin, spleen and kidneys. The instances of atrophy from disturbed innervation are less easy to discriminate, except where there is actual paralysis. In two distinct diseases, however, *progressive muscular atrophy* and *infantile or essential paralysis*, loss of power in the muscles is followed by a remarkable wasting, far more rapid than that which results from disuse alone. Division of the nerve of a limb produces rapid wasting of the muscles no longer used, and this is accompanied in the end by some diminution in the size of the bones and accessory parts. Local atrophy of the skin is sometimes seen in regions limited by the distribution of a nerve, especially some branch of the fifth, and more extensive atrophy of one side of the face or head, equally marked out by nervous distribution, and resembling some cases of congenital atrophy, has also been, though very rarely, observed. These facts raise the interesting question whether there are 'trophic nerves'. Without discussing this question, it may be pointed out that the nerves which delineate an atrophic region are always motor or mixed branches, never solely sensory.

Disuse produces atrophy only in organs whose functions are active and constant, such as nerves and muscles. Nervous tissue wastes constantly, and sometimes rapidly when currents cease to traverse it. This is seen not only in the nerves of paralyzed limbs, but even in the nerve-centres, where any interruption of the nervous channels, either above in the cerebrum, or below in the nerve-trunks, is followed by degeneration, ending in atrophy, of the whole nervous tract leading from the cerebral cortex to the peripheral termination—so called *secondary degeneration* of the cord. In muscular tissue the wasting is almost as constant, but hysterical paralyses make an exception, the helpless limbs preserving their nutrition in a surprising manner. In organs whose functions

are intermittent or periodic, disuse does not appear necessarily to produce atrophy, as is seen in the ovaries, testicles, and mammae.

That excessive stimulation or over-work may produce atrophy is seen in degenerative diseases of the nerve-centres arising from undue mental activity; and of the sexual organs from excessive indulgence.

Unexplained Atrophies.—Cases of local atrophy occur of which it is impossible to give any satisfactory explanation. Such are the conditions known as linear atrophy of the skin; some remarkable cases of atrophy of bone, especially of the skull (*fragilitas ossium*), and of some parts of the cerebrum. We may have to attribute to changes of the latter class just mentioned, certain peripheral atrophies, without being able to account for the original lesion.

It is possible that deficiency of special kinds of food may lead to atrophy of special organs—thus deficiency of lime may make the bones soft, and deficiency of iron arrest the development of blood-corpuscles; but even these familiar instances must be accepted with a little reserve. In the same way it is still doubtful whether any special drugs, such as iodine, can produce atrophy of special glands.

PATHOLOGY.—Wasting may occur simply, or as a consequence of change of substance, or from the intrusion of some new material; in other words, there may be *simple atrophy*, atrophy from *degeneration*, or atrophy by *substitution*. The first is probably rare; generally some change of substance occurs. The most frequent degenerative process is fatty degeneration; the albuminous substance being converted into or replaced by fat, which, if afterwards absorbed, leaves a void. Organs thus affected may be apparently enlarged, though the original substance is wasted. Atrophy from substitution is seen when the connective tissue of an organ, for instance, increases, compressing and destroying the other tissue-elements, and these not being renewed when the newly-formed connective-tissue is absorbed, the whole organ is diminished in bulk. This is seen in all the changes called cirrhosis or fibroid degeneration, as in cirrhosis of the liver and kidneys.

TREATMENT. No general rules can be laid down for treating all cases of local atrophy. Where the blood-supply is deficient, we have rarely any means of supplementing it; where innervation is at fault, it is seldom under our control. In general, harm rather than good results from any attempt to attract blood by artificial irritation. In the case, however, of atrophy from disuse of the nerve-muscular system, a line of treatment, and more especially of prophylaxis, is very clearly indicated; that is, to keep the muscles in exercise by artificial means, particularly by electricity, or by the processes of friction and kneading, known as *passive motion*. In this way so much of the atrophy as is due simply to disuse may be checked for the future, and even the past loss reinstated. We shall, moreover, never do harm by attempting to supply some special kind of food which appears to be deficient, as iron for the blood and phosphorus for the bones or nervous system.

J. F. PAYNE.

AUDITORY NERVE, Diseases of. See *EAR, Diseases of*; and *HEARING, Disorders of*.

AURA (*αἶψα*, a breeze).—A peculiar sensation, subjective in origin, immediately preceding an epileptic or hysterical convulsion, and named respectively *Aura Epileptica* and *Aura Hysterica*. The word was originally adopted because the sensation is often described as that of the passage of cold air or light vapour from the trunk or extremities to the head; but it has been extended so as to include any phenomenon, whether sensory or motor, that ushers in a fit of epilepsy or of hysteria.

AURAL DISEASES. See *EAR, Diseases of*.

AUSCULTATION (*ausculto*, I listen).—A method of physical examination, which consists in listening over various parts of the body, either by the direct application of the ear (*immediate auscultation*), or by the aid of special instruments (*mediate auscultation*), for the purpose of studying certain sounds produced in health and disease. See *PHYSICAL EXAMINATION*.

AUSCULTATORY PERCUSSION.—A method of physical examination in which the sounds elicited by percussion are studied by means of auscultation. See *PHYSICAL EXAMINATION*.

AUSTRALIA. See *APPENDIX*.

AUTOPHONIA (*αὐφών*, itself, and *φωνή*, the voice).—A physical sign obtained by studying the modifications of the resonance of the observer's own voice during auscultation. See *PHYSICAL EXAMINATION*.

AUTOPSY. See *NECROPSY*.

AZORES, St. Michael's.—Warm, very moist, equable climate. Mean winter temperature 58° F. Prevailing winds N. and E. See *CLIMATE, Treatment of Disease by*.

AZOTURIA.—A condition of the urine in which there exists an absolute and relative excess of urea, without accompanying pyrexia. See *URINE, Morbid Conditions of*.

B

BACILLUS (from *bacillum*, a little staff) is the name now given to certain filiform *Bacteria* which have assumed much importance of late, principally because of their constant presence in the blood and tissues in splenic fever and malignant pustule. See *LEPTOTHRIX*, and *BACTERIA*; also *PUSTULE, MALIGNANT*; and *BACILLI* in *APPENDIX*.

BACTERIA (*βακτηριον*, a rod) are some of the lowest known forms of life. They most frequently exist as minute rod-like bodies, about $\frac{1}{1000}$ inch in length, with a slight median constriction. They may be larger or smaller than this, and may present minor variations in form. They swarm in all putrefying solutions and mixtures of organic matter, and in many fermenting fluids in which the chemical changes are not accompanied by an emission of stinking gases. In fluids belonging to the latter category, the typical *Torula* or yeast-cell may be met with, as well as organic forms strictly intermediate between it and the typical Bacterium. From a chemical point of view, it is admitted that no absolute line of demarcation can be drawn between the intimately related processes of *putrefaction* and *fermentation*; whilst from a biological point of view we are similarly unable to erect any impassable barriers between the organic forms which are found as part of the products of change in putrefying and fermenting fluids respectively. It is unquestionably true that typical *Bacteria* are most frequently met with in putrefying fluids; whilst, on the other hand, typical *Torulae* are only present in some fermenting fluids. But the rather long rod-like bodies, which have been hitherto named *Vibriones*, and the still longer filaments mostly known as *Leptothrix* (see *LEPTOTHRIX*), are unquestionably capable of being derived from ordinary *Bacteria* in certain media.

In the most highly putrescent fluids *Bacteria*

are usually found to be very small, because, though the total bulk of living things rapidly augments in such fluids, the individual units (in consequence of the frequency with which a process of fission takes place) do not increase in size. In less putrescent fluids, however, where the chemical changes constituting the putrefactive process take place more slowly, the living forms also appear and grow with less rapidity; and owing to the co-existence of a lower frequency of fission or spontaneous division amongst such individual living units, they often attain a larger size. They then appear, according to their length, either as *Vibriones* or as *Leptothrix* filaments. These are plain, jointed, or monilated, according as partial segmentation is absent, has taken place rarely, or has occurred so rapidly as to give what would have been a plain filament the appearance of a string of beads.

Concerning the question of the precise relation of organisms to the processes of putrefaction and fermentation, opposite opinions are at present held. Believers in Pasteur's germ-theory maintain that they are invariably the initiators of these chemical processes; whilst those who reject this theory, as being too exclusive, contend that putrefaction and fermentation may be initiated in the absence of *Bacteria* and their germs. Those holding the former view believe that *Bacteria* are only capable of being derived from pre-existing organisms of like kinds; whilst those who reject it contend that particles of living matter, which develop into *Bacteria*, may be generated from the organic compounds dissolved in fermentable fluids, and that such particles of living matter are, in fact, just as much products of the fermentative process and of the fluid in which it occurs, as are the gases simultaneously generated therefrom. According to this view, these lowest living units bridge the gap hitherto held to exist between living

and so-called dead matter, and afford an illustration of the natural independent origin of chemical compounds so complex and endowed with such attributes as to win for them the name of 'vital' compounds (See *Proceedings of the Royal Society*, No. 172, 1876, pp. 149-156.)

Pasteur's 'Vital theory' of fermentation is one of great importance both to chemists and biologists, and it also forces itself upon the attention of medical men, as the parent of another doctrine which has of late assumed great prominence in relation to the science of medicine—the doctrine, namely, that lower organisms allied to those met with in putrefying and fermenting media are causally related to certain morbid processes with which they either do, or are said to coexist. Bacteria and their allies are as uniformly coexistent with a few general diseases and certain local morbid processes as they are with putrefactions and fermentations, so that the same general question as to the precise significance of this coexistence again presses for solution. Are the organic forms associated with such morbid processes the sole causes or inciters of these processes? or are they consequences (i.e. concomitant products) of pathological processes which have been initiated in their absence? The former view is warmly supported by many who regard bacteria and allied organic forms as the contagious elements of such communicable diseases, and many of these same pathologists, resting upon analogy, wish to extend their theory, so as to make it applicable to many other communicable diseases with which organic forms have not as yet been shown to be correlative.

Thus, just as certain chemists hold that Bacteria and allied forms are the causes of all fermentations and putrefactions, so certain pathologists either do actually, or are inclined to maintain that bacteria and allied organisms of common or of special kinds are the causes of all communicable or contagious diseases. According to such chemists all *ferments* are living organisms; and according to such pathologists all *contagia* are allied living organisms.

The coexistence of organisms is one which obtains for almost all fermentations, but only for a few of the communicable diseases, so that any argument deducible from such mere coexistences in favour of the causal relationship of the organisms, is much stronger in the case of fermentations than as regards diseases. Yet, in spite of the almost universal coexistence of organisms with fermentations, it is still necessary for us to ask whether they appear as causes or as effects of these phenomena. From this it may be judged how little the more limited 'facts of coexistence' should be allowed to influence our opinion on the derivative question of the relation of the lower organisms to disease. At least one of the reputed instances in which this coexistence of organisms has been dwelt upon, as showing that they are the causes of the morbid phenomena with which they are associated, has of late been dissipated, since in the case of the small-pox of sheep (*variola ovina*) the alleged organisms are now admitted to have no existence—certain appearances pro-

duced in the tissues by preservative media having been mistaken for organisms which have been elaborately described and figured. (See *Proceedings of the Royal Society*, No. 172, 1876, p. 140.) But even if all the alleged cases of coexistence of organisms with morbid processes were real, and if future investigations should show that such facts are more numerous than are at present imagined, still the multiplication of this evidence to any extent will never help us (any more than it has done in the case of fermentations) to solve the real question—whether such morbid processes are only caused and propagated by organisms, or whether they may at times come into existence independently?

The vital or germ-theory of fermentation would be broken down and become untenable whenever it is shown that fermentation can originate independently of the bacteria and their germs which appear as part of the process. Similarly, the germ-theory of disease would be refuted, if it could be shown that some of the morbid processes in question could originate in the absence of the living organisms which subsequently appear as part of the pathological products. The latter refutation, however, could never be made directly, since no living being could in any circumstance whatsoever be proved—in an experimental sense—to be beyond the possible reach of some of the alleged disease-germs. But inasmuch as this problem is, from its very nature, one which does not admit of experimental proof or disproof in the strictest sense of the term, and because this germ-theory of disease is clearly a derivative doctrine from the germ theory of fermentation, it must stand or fall with the germ theory of fermentation, which, fortunately, is capable of experimental proof or disproof. The question of 'spontaneous generation' comes, therefore, to be inextricably mixed up with the question of the truth or falsity of the germ-theory of disease, so that the study of the latter to the neglect of the former can only end in the propagation of vagueness and uncertainty. The real question is not as to the extent or frequency of the coexistence of organisms with local or general diseases, but the much more important one as to the nature of their relation to such processes. If they act as invariable and sole causes, then their presence is a matter of the deepest interest and importance. If, on the other hand, the organisms are not causes but rather concomitant products, their presence from a purely medical point of view is of trifling importance. The study of their growth and development would in that case be important only as adding to our knowledge of the structural changes pertaining to the diseases in question. See *Transactions of the Pathological Society*, vol. xxvi., and *Journal of the Linnean Society*, vol. xiv. See also the articles MICROCOCCI; PUSTULE, MALIGNANT; and ZYXIE.

BALANITIS — BALANOPOSTHITIS (*Balanus*, an acorn, and *posthion*, the foreskin).—**SYNON.**: Bastard Clap; Blennorrhagia Balani; Inflammatory Phimosis.

DEFINITION.—Inflammation of the opposing surfaces of the glans and prepuce; sometimes acute—even gangrenous, and sometimes chronic. A purely local affection; frequently, but not necessarily, of venereal origin.

ÆTIOLOGY.—Balanitis is much less common than urethritis, being met with at the Lock Hospital in the proportion of one to twenty-four of the latter. It may be either primary; or consecutive to chancres, syphilitic eruptions, warts, accumulated smegma, variolous pustules, or gonorrhoea. When primary, the common *pre-disposing cause* is a long, narrow foreskin. Fournier attributes two-thirds of the cases of balanitis to a long prepuce with insufficient cleansing; about one-third to irritation by chancres and gonorrhoeal pus; and a very few to other causes.

SYMPTOMS.—The symptoms of balanitis depend on the intensity and extent of the inflammation. In the simplest form there is heat and itching of the furrow, slight redness of that part, with a milky or yellowish secretion. When the inflammation is more severe and extended, swelling and pain are added, the other symptoms are more marked, and characteristic excoriations appear. They are irregular, shallow, never extending more deeply than the epithelium, but often coalescing into large raw chafings. An abundant yellowish-green matter of offensive odour lathes the surface. When the urine trickles over these excoriations there is severe smarting pain. If still further irritated, the foreskin swells enormously, is divided at the free border by deep creases, and can no longer be turned back. Aching, smarting, great tenderness, and painful erection, often accompanied by constitutional disturbance and fever, are present.

COMPLICATIONS.—The cellular tissue and the lymphatic ducts of the foreskin and sheath, or the lymphatic glands, may inflame to suppuration, to ulceration, and, in persons enslaved by any cause, even to gangrene. Sloughing begins on the inner surface of the foreskin at the upper part; seldom to much extent, though the whole prepuce, except the frenum, may be lost, and when cicatrization sets in the organ appears circumscribed. Paraphimosis is caused by imprudent retraction of a swollen foreskin. Warts keep up chronic posthitis of the furrow. Adhesions, usually at the corona and the furrow, may attach the prepuce completely to the glans. Thickening and phimosis are not uncommon after repeated attacks.

COURSE.—The duration of balanitis depends

on the anatomical condition of the parts. When remedies can be easily applied, it is not more than three or four days. With phimosis, the course is severe, and the duration is indefinite; even when limited to the furrow, posthitis is often obstinate.

DIAGNOSIS.—This is easy when the parts can be exposed. *Herpes* is distinguished from balanitis by small grouped round ulcers, limited to one or two points of the mucous surface, without general congestion. *Simple chancre* has well-defined undermined edges and a spongy surface. The *syphilitic sore* has the indurated base and enlarged lymphatic glands. When there is phimosis, the discharge may come from the urethra or from a chancre. If from the urethra, it can be usually seen escaping thence, and there is pain along the penis, with other signs of urethritis. A chancre under the foreskin is betrayed by a hard and tender point, and after a few days consecutive sores usually appear at the orifice of the prepuce.

PROGNOSIS in the primary form is always good. If the complaint is secondary or symptomatic, gangrene may result.

TREATMENT.—The chief indication is to keep the inflamed surfaces separate. After washing and thoroughly drying, the excoriations should be touched with a 10-grain solution of nitrate of silver, and a bit of dry lint laid on the glans before the foreskin is drawn forward. If there is phimosis, frequent injections of tepid water, and twice daily of a 5-grain solution of nitrate of silver must be thrown to the farthest part of the foreskin with a long-nozzled syringe. Leeches to the groins, and opium internally, as well as in injections, relieve pain. Acupuncture gives vent to simple œdema, but tend to accelerate gangrene with hrawny tension and erysipelatous redness. Incisions, if needed should be free; one on each side, carried quite back to the furrow. The upper half of the foreskin can then be easily turned back, and the subsequent deformity is less than if the foreskin is divided at the dorsum. In paraphimosis, before replacing the swollen foreskin, the tension should be relieved by acupuncture and astringent lotions, or by incisions if needed. BERKLEY HILL.

BALDNESS.—**SYNON.**: Alopecia.

DESCRIPTION.—Baldness or loss of hair presents an extensive range of variation in degree, from moderate thinness of the hair, such as occurs in *Defluvium capillorum*, to complete baldness—*Alopecia calva* or *Calvities*, the latter not limited to the scalp alone, but involving eyebrows, eyelashes, beard, and every hair of the body. Instead, however, of being *general*, baldness may be *partial*, affecting more or less of the surface of the scalp for example, the summit and forehead in men, and the summit and occiput in women. One remarkable form of partial baldness has been denominated *Alopecia areata*, or simply *Area*, and as this was described by Celsus, it has likewise been called *Area Celai*. *Area* occurs suddenly, and is a mere falling-off of the hair over a space of circular figure; there may be one or more of such *Areae*, and sometimes *Area* is only the beginning of *Calvities*. *Area* is likewise occasionally met with in the whiskers and beard.

PATHOLOGY.—The pathology of Alopecia is a loss of nutritive power of the skin, sometimes progressive and consequent on advancing age, as in general baldness; and sometimes limited to a narrow district of small extent, as in Area. This fact is very evident in the latter form, inasmuch as, conjoined with the sudden dropping-out of the hair, the integument is pale and thin, poorly nourished, somewhat anæsthetic, and thinner in the centre than at the circumference; while the hairs which remain at the periphery are altered in structure, clubbed and broken off.

ÆTIOLOGY.—The causes of Alopecia are exhausted nutritive power of the skin; nerve-paralysis in the case of Area; syphilis; and local injury. The Alopecia of syphilis follows the plan of distribution of its exanthem. Partial Alopecia may result from a blow; from the accidental tearing out of a lock of hair; from the sting of a bee; from nervous shock; or from other causes.

TREATMENT.—This consists in the restoration of nerve-power and nutritive power; and in local stimulation. The best applications for the latter purpose are the stimulating liniments of the British Pharmacopœia; e.g. liniment of ammonia, compound camphor liniment, and the liniments of chloroform and mustard; or the acetum cantharidis properly diluted for general Alopecia, or applied with a brush in its concentrated form for Area. In the treatment of the latter, ammonia, turpentine, and the compound tincture of iodine are likewise useful; while for syphilitic Alopecia the white precipitate ointment with camphor is the best local application, conjoined with an anti-syphilitic constitutional treatment.

BATHS.—Baths may be regarded as simple; and compounds, mediated, or artificial. They may be used in the form of liquid, vapour, or air. We shall consider them under these heads in the following description:—

A. SIMPLE BATHS.—1. Simple Liquid Baths.

1. *The Cold Bath.*—By a cold bath is meant the immersion of the body in water below the temperature of 70°. Anything below 50° is considered a very cold bath. The first effect of

the bath is a sensation of cold amounting almost to shivering, with slight gasping for breath. If the bath is continued for more than two or three minutes, the temperature of the skin is diminished; and if it is protracted, the blood and the subjacent tissues lose a little heat, but this does not generally occur till after quitting the bath. If the cold is intense and prolonged, there is a certain degree of numbness of the skin; while the pulse becomes small, and may fall from ten to twenty beats in the minute. After a short time (the colder the water the shorter), reaction takes place, bringing redness to the skin and increase of temperature, with a certain amount of excitement; but if the bath be continued, the depression returns. The immediate action of the cold bath is to cause the capillaries to contract and repel the blood from the surface, while by its operation on the peripheral extremities of the nerves, it acts upon the central nervous system. In its more remote effects, the cold bath accelerates the transmutation of tissues, augmenting the excretion of carbonic acid and of urea from the system, and, as a consequence, increasing the appetite.

The body is usually immersed at once in cold water, but the shock of this may be diminished by first using tepid water, and then gradually adding cold to it.

The effect of a cold bath depends much on its duration. Brief immersion, that is for three or four minutes, makes both the depressing and the exciting action less; a longer duration, say of ten to fifteen minutes, increases both actions, but if the bath be very protracted, the continued abstraction of heat produces depression only. The effects of a cold bath are less intense, if the bather is able to keep himself in motion, and especially if he swims.

2. *The Warm Bath.*—A warm bath of 96° to 104° produces no shock to the system; it causes a moderately increased flow of the circulating fluids to the surface, augmenting the frequency of the pulse; and scarcely affects the respiration. There is not the depression or the excitement of a cold bath. It rather retards the transmutation of tissues. With a hot or very hot bath—from 104° to 114°, the central nervous and circulatory systems are more affected. The frequency of the pulse increases greatly. The respiration becomes anxious and quickened. The skin is in a hyperæmic condition, and a free perspiration breaks out.

3. *The Tepid Bath.*—Tepid baths of the temperature of 85° to 95°, are intermediate between cold and warm. Their effects seem to be confined to the peripheral extremities of the nerves, and they do not excite the nervous centres or the circulatory system. Neither the pulse nor the excretions and secretions are affected. As no heat is confined in the system or taken from it, there is no reaction, and the animal temperature is unaltered.

It need scarcely be said that drying and rubbing after a bath materially assist its action on the skin; or that, according to circumstances, it may be convenient to order a whole bath, a hip-bath, or a slipper-bath. The foot-bath is a very useful and convenient one, especially when some stimulant substance is added to the simple water.

Wet packing and the various processes of hydro-pathy, and those powerful agents hot and cold affusion, whether as shower-baths or as douches, are described in the article on HYDROPATHY.

The duration of a bath must depend on a variety of circumstances, for instance, on the age and constitution of the patient, on the nature of his malady, and on the temperature of the bath. It may vary from a few minutes to many hours. A very hot or a very cold bath can be supported for a much shorter time than a tepid one.

ACTION AND USES.—Cold baths are indicated for the strong, for youth, and for manhood, warm baths for the delicate, for women, for early childhood, and for old age. Tepid baths are suitable for almost all constitutions, sexes, and ages. Cold baths may in a general way be considered tonic and bracing; they are useful when judiciously employed in many nervous affections, as in chorea and hysteria, and they are the best of all for general hygienic purposes. Of late years they have been specially employed in the treatment of fever (see article TEMPERATURE). The great value of warm baths, besides their hygienic employment, as better detergents than cold ones, is in soothing and reducing excitement; in relieving spasms, such as colic and retention of urine, in the convulsions of children, combined with the affusion of cold water on the head; in cases of gout and rheumatism; and generally when action on the skin is desired. Where prolonged immersion is wanted, tepid baths are indicated, as in calming many chronic nervous disturbances, and in many cutaneous affections.

As to contra-indications, all baths, and especially prolonged and even tepid baths are not suited for the asthenic. Both hot and cold baths are to be avoided where there is a weak, fatty heart, or any tendency to apoplexy. No one should ever enter a cold bath when exhausted, and such baths are also contra-indicated when there is a tendency to congestion of internal organs. Under such circumstances a warm bath is usually both safer and more refreshing. The too long and too frequent use of hot baths is debilitating.

II. The Simple Vapour-Bath.—A vapour-bath is one in which the skin is exposed to the action of hot water presented in the form of vapour. The vapour-bath may be taken in a box with the head included or not; or in the more common form of the Turkish or Russian baths, where a large room is filled with vapour, and where therefore the vapour is inhaled; or by vapour obtained from a small and suitably constructed apparatus, which vapour may be diffused over the whole body or directed to a particular part. A very simple apparatus for the vapour-bath may be prepared by placing under a chair a shallow earthenware or metallic pan, containing boiling water to the depth of three or four inches, and from which abundant vapour can be obtained by placing in it one or two red-hot bricks. The patient sitting on the chair, surrounded by blankets and other suitable covering, will receive the full benefit of a vapour-bath. Vapour-baths produce profuse perspiration, and act in cleansing the skin much as hot-water baths do, only more powerfully. Vapour being a

slow conductor, does not act so fast on the body as water. Vapour-baths can be borne hotter than warm-water baths, but their use cannot be continued so long, as vapour interferes with radiation of heat from the body. In such baths a heat of more than 122° is not borne comfortably. The vapour-bath, though falling considerably short in temperature of the air-bath, raises the heat of the blood somewhat more. The great virtue of these baths is in their sweat-producing properties. The average loss of perspiration by the use of a Russian bath has been set down at from $\frac{1}{2}$ lb. to 3 lbs. In the Russian bath a slight degree of stimulation of the skin is caused by switching it with twigs of birch, and the alternation of depression and excitement of the cold bath is obtained by placing the patient, when in a state of profuse perspiration, under a douche of cold water.

III. The Simple Hot-Air Bath.—There are two forms in which the hot-air bath is administered: according as the patient does not or does breathe the heated air. The action of the latter closely resembles that of a vapour-bath, but differs from it in not impeding the respiration, as the latter does by depositing moisture in the bronchial tubes. The lungs, instead of requiring to heat up the inspired air, are subjected to a temperature above their own. Hot-air baths favour the highest degree of perspiration, while the moisture of vapour baths somewhat retards it. If they are very hot, they raise the temperature of the body by several degrees.

As the arrangements for vapour- and hot-air baths are practically the same (except that in the latter it is attempted to exclude all vapour from the *calidarium* or *sudatorium*, the hottest room), the following description of an ordinary hot-air bath, the arrangements of which are closely copied from the Romans, will answer for both.

The patient after undressing first goes into the *tepidarium*, which has a temperature of 113° to 117°, in which he remains until the perspiration bursts forth, which happens in from twenty-five to forty minutes. He next proceeds to the hottest room or *calidarium* (in which the air is heated by hot-air pipes which are inserted in the walls), of a temperature of 133° to 140°, and remains there until the perspiration runs down his skin in twelve to eighteen minutes. An attendant then rubs off the perspiration with a woollen glove, and kneads all the muscles for four or five minutes. The patient next betakes himself to the *lavacrum*, where he has water poured over him of the temperature of 81° to 86°; next, the whole body is soaped over, the suds are rubbed off, and the patient goes to the *frigidarium*, where he lays himself on a couch and waits till his skin is completely dry. This may occupy twenty-five to thirty minutes, when the patient dresses and leaves the bath greatly refreshed.

Such is a brief account of these baths, the revived use of which is at present so general. The arrangements vary in detail. For ordinary purposes it is easy to furnish either vapour- or hot-air baths. A great variety of apparatus have been invented for this purpose, which resolve themselves into this, that the patient should lie in bed or on a seat, and have the bed-

clothes or other covering secured from contact with him by the employment of a framework or cradle. Beneath this hot air or vapour is introduced, either directly or indirectly, from a suitable apparatus.

The Sand-Bath.—We may here mention baths of sand, which are a very old remedy. Of late years establishments for supplying them have sprung up in various towns. They are a convenient way of applying dry heat either locally or generally, and are employed in chronic rheumatism. Bags filled with heated sand are useful in hospital and in domestic practice.

Uses.—Both hot-air and vapour-baths are indicated when increased action of the skin is desired. They are used most for the cure of catarrhs, of neuralgic and rheumatic pains, and sciatica. They have also been much employed for reducing obesity. They are useful for general hygienic purposes, but are apt to be given too indiscriminately. Hot-air and vapour-baths are often locally applied with great advantage to a hand, or leg, or arm, in rheumatism or thickened joints.

B. COMPOSITE, MEDICATED, OR ARTIFICIAL BATHS.—A great variety of substances have been used in baths at different periods. We must confine ourselves to such as are at present in use and appear to be of some real value, omitting even some that are employed, such as baths of iodine, of iodide of potassium, of iron, of fermented grapes, and of whey.

1. Composite Liquid Baths.

1. The Sea-Water Bath.—The average amount of salts in sea-water may be set down at 3 per cent.; this may therefore be considered a suitable strength for ordinary salt baths. The quantity commonly used in London hospitals is about 9 lbs of salt to 30 gallons of water. Some use bay salt, others Tidman's. Owing to the high price of sea-salt in inland continental places, various natural salts, some of them containing a comparatively small amount of chloride of sodium, have been suggested as substitutes, and also, for economy's sake, 22 to 25 gallons have been set down as a minimum amount of water for the bath of an adult. The value of these substitutes can only be determined by observing the degree in which they stimulate the skin. Apparently it does not matter much what particular salt is employed to produce the stimulation. A salt-bath can of course be increased to any strength by the addition of salt, or of the mother lye as it is termed.

The chief uses of salt-water baths are as tonic remedies, especially for the young, when there is any tendency to scrofula or chlorosis; also in convalescence from many diseases.

2. Alkaline Baths.—Alkaline baths may be made by adding 6 ounces of crystallised carbonate of soda, or 3 ounces of carbonate of potash, to 25 or 30 gallons of water. Alkaline baths are of use in a great variety of cutaneous affections.

3. The Corrosive Sublimated Bath.—Baths of corrosive sublimate are occasionally employed. They are commonly made by adding 3 drachms of corrosive sublimate and 1 drachm of hydrochloric acid to 30 gallons of water. They are employed in some skin-affections, and in secondary syphilis.

4. Sulphuret of Potassium Bath.—Baths of sulphuret of potassium are made by dissolving from 4 to 8 ounces of that salt in 25 to 30 gallons of water. A little dilute sulphuric acid is sometimes added. These baths have long been extensively employed in the treatment of cases of skin-disease in which the sulphur that they contain is indicated.

5. The Nitro-Muriatic Acid Bath.—The nitric or rather the nitro-muriatic acid bath is made by adding nitro-muriatic acid to water. The ordinary proportion is one ounce of acid to one gallon of water. The discolouring action on clothing makes a full bath of this kind inconvenient for domestic use, and it is best to take it in a bathing establishment. For the ordinary purposes of a foot-bath at home the old directions of Dr. Heleus Scott, who introduced the use of the acid, are sufficient. The vessel must of course be of wood or earthenware. Dr. Scott added four to six ounces of the acid to three gallons of water. This made a rather strong foot-bath. The patient was to keep his feet immersed for thirty minutes: and the bath was to be repeated every other day for two or three weeks. The axilla, the groin, and the region of the liver were to be sponged with the acid solution. The bath causes slight tingling of the skin and a taste in the mouth, and is believed occasionally to produce salivation. This bath has been used very extensively in India and in England in liver affections. There is difference of opinion as to its value, many have great confidence in it.

6. The Bran Bath.—The bran bath is made by boiling four pounds of bran in one gallon of water, straining, and adding the liquor to a quantity of water sufficient for a bath. Such a bath is useful in allaying the irritability of the skin, and also in diminishing the stimulating effect of other baths.

7. The Fucus Bath.—This is made by adding a decoction of sea-weed, or the sea-weed chopped up, to an ordinary bath; it will become more or less gelatinous if enough be added. Such baths go popularly by the name of *Ozone baths*, and they contain a certain amount of chloride of sodium and a minute proportion of iodine. They are useful in the same cases as sea-baths.

8. The Mustard Bath.—An extremely useful stimulating bath is the well-known mustard bath, which is made by adding a handful or two of mustard to the ordinary hot bath. The pediluvium is its most useful form.

9. Pine Baths.—Baths of the balsam of pine-leaves may be prepared extempore by making decoctions of the fresh leaflets at certain seasons; but the usual way is to add about one pound of the extract which is prepared from the leaves, and is everywhere for sale—at least in Germany. The extract dissolves in the bath, which is then ready for use; but of late it has been usual to add a small amount of an essence which is also prepared from the leaflets. It floats to the surface of the water, and attaches itself to the person on leaving the bath, and its aroma is grateful. Of course the quantity of the extract to be employed depends on its strength. These baths are at present largely employed. They are slightly stimulant, and are much used in hysterical, rheumatic, and gouty

affections, and also as an adjunct to the internal use of mineral waters.

10. *Baths of Conium, Lavender, &c.*—Aromatic or sedative baths are prepared by adding a decoction of lavender, hyssop, or conium to an ordinary bath.

It is scarcely necessary to add that, as a rule, all composite liquid baths should be of a temperature a little above the tepid; and that their strength, and the time that the patient is to remain in them, must be determined by the special circumstances of the case.

11. *Composite Vapour-Baths.*—Vapour-baths impregnated with *fer balsam* are popular, and are considered to be more powerful in their operation than pine-baths. The vapour which rises in making the decoction of pine leaves is conveyed to a box in which the patient is enclosed.

Aromatic vapour-baths may be given by making the steam of hot water pass through bunches of fresh aromatics (*conium, lavender, &c.*) before reaching the box in which the patient is placed. Such baths may be useful in hysteria.

III. Composite Air-Baths.

1. *Sulphurous Acid Bath.*—A valuable mode of applying sulphur in the form of a bath is by using its fumes—in other words, sulphurous acid. The patient is seated on a cane-bottomed chair, and his body is encircled with a cradle, over which oil-cloth is thrown, the head remaining uncovered. Sulphur is placed on a metallic plate, to the lower surface of which the flame of a lamp is applied, when sulphurous acid is disengaged. This bath is less used in cutaneous affections than formerly.

2. *The Mercurial Vapour-Bath.*—Very similar is the mode of applying the fumes of mercury. Under the chair are placed a copper bath containing water, and a metallic plate on which are put from 60 to 180 grains of the bisulphuret or of the grey or red oxide of mercury. Spirit lamps are lighted under the bath and under the plate. The patient thus experiences the effects both of aqueous and of mercurial vapour. At the end of five or ten minutes perspiration commences, which becomes excessive in ten minutes or a quarter of an hour. The lamps are then to be extinguished, and when the patient becomes moderately cool, he is to be rubbed dry. He should then drink some warm liquid and remain quiet for a time. This has often been a favourite mode of treating secondary syphilis with some practitioners. Calomel, in quantities of from 20 to 30 grains, is administered in a similar manner, under the name of the *Calomel Bath*. It may be given locally by a suitable apparatus.

BELL-SOUND. A peculiar physical sign associated with pneumothorax. See PHYSICAL EXAMINATION.

BELL'S PARALYSIS. (Named after Sir Charles Bell.) A synonym for paralysis of the facial nerve. See FACIAL PARALYSIS.

BERIBERI.—SYNON.: Barbiéri, and numerous other local names.

DEFINITION.—A disease characterised by anæmia, anasarca, degeneration of muscular tissue, effusion into the serous cavities, debility, numbness, pain, and paralysis of the extremities, especially the lower; præcordial anxiety, pain, and dyspnoea; scanty and high-coloured urine and in some cases drowsiness or sleepiness. Beriberi occurs in a chronic and an acute form, in the latter often proving rapidly fatal from exhaustion, syncope, or the formation of cardiac or pulmonary conglua.

ETYMOLOGY.—The etymology of the word Beriberi is obscure. Horkkots suggests the Hindi word, *Bhêre*—a sheep—from the fancied resemblance of the gait of persons affected to that of sheep. *Soond-bhêre* comes from the words numbness and sheep. *Soond-ko-baee* signifies numbness and rheumatism. *Bhêr-bheri*, a Hind. word, signifies a sore, a swelling. Mason Good says that Bontius introduced the word Beriberia, and tells us that it is of Oriental origin. Carter suggests *Bhari*, sailor, from *Bahr*, the sea; and *Bhagr*, shortness of breath. As the disease is seen among African and Arab sailors, this is probable. Some think it is derived from a Cingalese word meaning weakness, first applied to a variety of conditions, the result of scorbutic, malarious, rheumatic, and anæmic cachexiæ, on the Malabar Coast.

GEOGRAPHICAL DISTRIBUTION.—Beriberi prevails endemically in Ceylon; and in India, on the Malabar Coast, and in the Northern Circars, between 13° and 20° N latitude, extending inland from forty to sixty miles. It is known in other parts of India, probably occasionally all over the peninsula; in Barmah and the Malayan peninsula; amongst the crews of ships trading to ports in the Persian Gulf, Red Sea, coast of Africa, Bay of Bengal, Singapore, Siam, and the islands of the Indian Archipelago, and in the Australian seas. On the West Coast and other parts of Africa beriberi also occurs, and is known as the *sleeping sickness*. In Europe *pernicious anæmia* is possibly the same disease. Beriberi is also met with in South America, and probably wherever certain conditions of food, water, soil, climate, and mode of life coexist.

ÆTIOLOGY.—All observation tends to show that beriberi occurs where causes of debility have for some time operated, especially in the climates and localities previously mentioned, such as certain conditions of soil, air, and water; exposure to great alternations of temperature, especially when accompanied by wet, fatigue, mental and physical depression; food deficient in quantity and quality or variety; previous exhausting diseases; malaria, and other undefined atmospheric and telluric influences—all, in fact, that tends to depress the vital energies, impoverish the blood, and starve the nerve-centres. The symptoms, it is said, seldom begin to appear within ten months or a year after first exposure to these causes. Beriberi has been ascribed by Ranking to disease of the kidney, but there is no evidence to prove that it is due to this cause, or indeed to structural changes of any of the viscera. Morehead refers it rather to a scorbutic riga and in some respects it does resemble

scorvy; it may probably, also, be a consequence of the cachexia that so often results from long residence in a malarious climate, especially when that has been accompanied by exposure, privation, and excessive exhaustion of the vital powers. In such, the most complete anemia, with debility, may occur, independently of the existence of organic visceral disease, though naturally they will be intensified where such disease is present.

ANATOMICAL CHARACTERS.—Serous fluid is effused generally—in the areolar tissue, in the lungs, bronchæ, heart, and abdominal viscera. The cavities are, like the tissues, soaked with watery effusion. The tissues are soft and degenerate. Muscular fibre is fatty, especially that of the heart, which is often enlarged and dilated. The kidneys are enlarged, anemic, and softened.

PATHOLOGY.—The recent discovery by Mr. T. Lewis in India, of the embryo of a nematode worm in the blood of persons suffering from chyluria (see CHYLURIA), lymphorrhæa, and elephantiasis, of which diseases it appears to be to some extent the cause, suggests inquiry whether a similar hæmatozoon may not also be in some way concerned in inducing beriberi. Fousgrives and Leroy de Mericourt describe beriberi as general dropsy with a rapid course, no albuminuria, and weakness and loss of sensibility in the lower limbs. Dropsy commences as anasarca, and extends to the serous cavities. Though hepatic, splenic, or renal complications may exist, and intensify the severity and hasten the progress of the general symptoms, they are not essential concomitants of the disease, but appear to originate in a spæmic state of the blood, and to be kept up by its progressive imperfect elaboration. The resulting partial starvation of the cerebro-spinal nerve-centres, and the serous effusion into and amongst them, sufficiently account for the paralysis which, in severe cases, characterises this disease.

SYMPTOMS.—Beriberi presents itself under a *chronic* and an *acute* aspect, rarely, it is said, ever occurring in either form, until after an exposure of some months to the exciting causes. The general symptoms may be said to be those of anemia and anasarca. Oedema pervades the limbs and body generally, accompanied with numbness, pain, heaviness, and loss of power, amounting in some cases to paralysis. Along with these symptoms there occur precordial anxiety, dyspnoea, irregularity and palpitation of the heart, pain at the ensiform cartilage, anemic murmurs, debility, and a small quick pulse, which at the outset may be rather hard and full, accompanied by dryness and heat of skin. The appetite is at first not impaired. Later there is coldness of the extremities; torpor of the bowels; scanty, high-coloured urine, of sp. gr. 1020 to 1040, but no albuminuria as a rule. According to Horton and others, excessive drowsiness and stupor attend some stages of certain cases of the disease; also pale, flabby tongue and blanched mucous membranes; occasionally hæmorrhage from the stomach and bowels; with petechial eruptions; an anxious look; a puffy, swollen, and sometimes livid face; and a peculiar tottering gait. Death results rapidly in some of the acute cases, with symptoms of effusion

into the thoracic and abdominal cavities, or within the skull, by exhaustion, syncope, or the formation of coagula, either in the systemic or in the pulmonary circulation. Beriberi frequently assumes a slight and modified form, indicated by anemia, numbness, and a certain amount of pain in the limbs; an anxious expression; disordered bowels, scanty urine; cold skin; a low, feeble, and irregular pulse; precordial pain or uneasiness, with palpitation; nervous depression; an unsteady, almost tottering gait; and a puffy face and neck. Dr. Paul says: 'I have met with a numerous class of cases that are not so serious (as the acute) or so often fatal, where the chief symptom complained of was burning of the feet.' Malcolmson describes this remarkable condition in connection with beriberi, to which, he says, it is allied—it is found to affect the soles and calves of the legs, the back, and occasionally the muscles of the legs.' It occurs in recent and slight examples of beriberi, and was first observed in the troops after the first Burmese war—sometimes in men who had not had beriberi; on the whole, Malcolmson thinks it is neither rheumatism nor beriberi, and may accompany or follow other diseases, as an indication of nervous debility.

In the *acute* forms of beriberi the symptoms are very severe and often rapid; and the mortality would indicate it to be second only to cholera in fatality. The chief symptoms are:—Rapid general anemia and dropsy of the cavities; scanty, almost suppressed urine; constipation; weak, irregular pulse; intense precordial pain; hurried, irregular, and painful breathing; occasional vomiting—sometimes of blood; swelling of the limbs, with numbness, pain, and paralysis, preceded by a feeble, tottering gait; all the symptoms of pleuritic and pericardial effusion; failing heart, and death either from syncope, or perhaps almost suddenly from embolism—in the most acute cases within a few days. In this acute form the affection is very fatal, but in the milder and more chronic form recovery is frequent. Acute cases often supervene in those who have suffered from the milder disease, or in those who are exhausted and anæmic from other causes.

TREATMENT.—Attention to diet, suitable clothing, and protection against vicissitudes of temperature, wet, and cold, are the best *preventive* measures. Bad hygiene and exhausting habits of life tend to promote the development of the constitutional condition in which the disease commences.

When beriberi is established these precautions are still necessary, and attention must be paid to the symptoms as they occur. Diuretics and diaphoretics relieve the oedema and dropical effusions. Tonics and stimulants give vigour to the weakened muscular fibre; while appropriate remedies and diet may improve the condition of the blood.

Acetate of potash, digitalis, and squill, and occasionally calomel, are said to favour the removal of the fluid. It is needless to say that the physiological action of mercury is to be avoided. Salines, hot-air baths, diaphoretics, and turpentine may at various stages be found useful. The object being to remove the fluid and

strengthen muscular fibre, quinine, i.e., and other tonics are an important element in the treatment. No remedies, however, will be of much avail unless the patient be placed in favourable hygienic conditions. Malcolmson speaks highly of two remedies—*tréak farook*, and *oleum nigrum*, which are considered to be very effective in the treatment of the disease, especially in relieving the dyspnoea and oedema, which proved very fatal until these drugs were introduced. The composition of the *tréak* is apparently generally unknown—it seems to be diuretic and stimulating, and probably not aperient unless combined with rhubarb, in doses of four to fifteen grains. The *oleum nigrum* is a stimulant and diaphoretic, given thrice daily, and has been found by Indian physicians to be very beneficial in some cases of beriberi. Dr. Aitken says that turpentine is a useful remedy. Ergotin, iron, and belladonna with zinc in the form of pill, accompanied with sea-bathing, were useful in this disease, as seen at Bahia. Nuxvomica has often been found serviceable in certain cases, as might be expected, and opium may be needed to allay pain and irritability. Hepatic and splenic complications need their appropriate remedies. Obviously the chief indications are to promote removal of the oedema; to regulate the functions of the abdominal viscera, to increase the action of the skin; and to give tone and vigour to the muscular fibre. By such measures can we alone hope to deal successfully with this profound form of cachexia.

JOSEPH FAYRE.

BIARRITZ in France, on the Bay of Biscay. A fashionable sea-side resort. The climate is considered to be bracing. See CLIMATE, Treatment of Disease by.

BILE, Disorders of.—Disorders of the bile held a large place in the medicine of antiquity, with the exception of the theories of Van Helmont and Paracelsus; the latter looking upon the bile as the balsam of life, and therefore incapable of begetting disease; the former regarding it as a mere excrementitious fluid, and therefore equally incapable of begetting disease. Disorders of the bile have, nevertheless, held their own quite into our time. It is common enough to hear persons speak of a 'bilious attack,' or 'being troubled with the bile,' expressions the survivors of the humoral pathology. The liver was formerly credited with most of the dyspeptic disorders of the stomach. As Sir Thomas Watson says, it is an organ often blamed most gratuitously and unjustly, but no educated or scientific physician would now think of attributing a gastric catarrh, or constipation, to an 'attack of the bile,' or to a 'sluggish liver.'

Physicians have arranged disorders affecting the bile under three heads—(1) diminished secretion of bile; (2) increased secretion of bile; and (3) secretion of morbid or altered bile. This division may very well be accepted as a convenient basis for the further discussion of biliary disorders, but it is nothing more than an hypothesis. It is likely enough that the bile, in certain diseases, changes its character as regards both its amount and constituent parts: but it cannot be denied that the means by which physicians are able to ascertain these changes can scarcely be

said to exist in ordinary cases. A common saying is that the patient must be making plenty of bile because the stools are high in colour. No reasoning can be more fallacious. The colour of the stools may be high if the feces be quickly swept through the intestinal canal, because there has been no time for the bile-pigment to be absorbed into the blood. Or the feces may be pale if they lie long in the bowel and the coloured matter absorbed. So that the colour of the stools is no sure sign of the poverty or abundance of the secretion of bile. In cases of pale, coloured feces purgatives often do good, not because they have any special tendency to increase the flow of bile, but because they hurry the feces out of the intestine, and thus give no time for the absorption of the bile, which, if it lay long in the bowel, would be absorbed, carried to the liver, and again excreted into the gall-ducts—the vicious circle of Schiff.

Nor is the analysis of the bile found after death in the gall-bladder of much value. Frerichs announced the presence of albumen in the bile in cases of congestion of the liver; but it is now generally thought that this appearance is due solely to a *post-mortem* transudation. Ritter also has described a colourless bile in which all the constituents of bile are present except the pigments. Most of his analyses were made on bile taken from the gall-bladder after death; but if the cystic duct be obstructed for any time, it is well known that the bile contained in the gall-bladder may become colourless without any real secretion of colourless bile having taken place in the first instance. It is impossible to be certain that the changes, which are found in the bile taken from the gall-bladder after death, have taken place during life.

The only source of what may be called knowledge of the disorders of the bile is observation of men or animals in whom biliary fistulae have been formed either by disease or by art. Unfortunately, the majority of such observations have been physiological or pharmacological; and but few are recorded of the changes which the bile undergoes in disease. Altogether contradictory experiments are recorded of the influence of the nerves and of the diabetic puncture of the fourth ventricle upon the secretion of bile. It is an admirable field for further research, but it will be seen that our present knowledge very closely approaches to complete ignorance.

It is disputed still whether the presence of bile in the stomach puts an end to the process of digestion. By many it is thought that the bile-acids throw down the albumen of the food, and with the albumen the pepsin. It is well known that in some disorders there is an inverted action of the duodenum, and bile is poured into the stomach, as in long-continued vomiting, for instance; thus the dispute has a practical bearing. The best treatment of this state would seem to be by saline purgatives.

Bile may also be taken up into the blood, and when this occurs, jaundice results (see JAUNDICE).

J. WICKHAM LAGO.

BILHARZIA.—This name was given by the writer to a genus of flukes discovered by Dr. Bilharz, of Cairo, in the portal system of human

blood-vessels, and the worm was subsequently found by the writer in the portal vein of a monkey. This trematode hæmatosoon was first described as a *Distoma*, but the species is now more generally known as the *Bilharzia hæmatobia*. It was originally found in the portal system, and Bilharz, Griesinger, Lautner, and others afterwards showed that this parasite also infects the veins of the mesentery, bladder, and other parts, producing a formidable disease which is endemic in Egypt, at the Cape, at Natal, and probably in other parts of the African continent, as well as in the Mauritius. The discovery that the endemic hæmaturia of the Cape of Good Hope is occasioned by the presence of *Bilharzia*, is due to Dr. John Harley, who detected the ova in the urine of a patient who had previously resided in Southern Africa. Dr. Harley's impression that he had to deal with a new species of *Bilharzia* has not gained general acceptance, but he furnished proof of the wide geographical distribution of this parasite, and he also added largely to our knowledge of its ravages.

DESCRIPTION.—This parasite, unlike nearly all the other known species of fluke, has the sexes separate, the females being comparatively slender worms, resembling filariform nematoids. During copulation the female is lodged in a long slit-like groove, or gynæcophoric canal, with which the abdomen of the male is furnished.

FIG. 2.—*Bilharzia hæmatobia*, male and female sexually combined. Magnified. After Küchenmeister.

FIG. 3.—Ovum of *Bilharzia hæmatobia* with contained embryo and free sarcodæ-granules. $\times 234$ diameters. Original.

The eggs, measuring from $\frac{1}{100}$ " to $\frac{1}{150}$ " in length, are peculiar, being either sharply pointed at one end, or furnished with a projecting spine, placed at a little distance from the hinder pole. This spine gives a point of resistance to the egg during the struggles of the embryo to effect its escape. Those who are interested in the organization of the ciliated embryos, and in the remarkable behaviour of the larvæ during their earliest stages of growth, will find the subject fully discussed in the writer's paper 'On the development of *B. hæmatobia*,' together with remarks on the ova of another urinary parasite, occurring in a case of hæmaturia from Natal, *Brit. Med. Journ.*, 1872.

TREATMENT.—The writer has pointed to the danger of treating cases of *Bilharzia* as if they were comparable to ordinary helminthiases. It is neither desirable to employ active drugs for the

expulsion of the parasite and its eggs from the bladder, nor is it prudent to attempt the employment of vermicides with the view of destroying the worms. As in *Trichinosis*, so in the *Bilharzia* disease, it is essential to support the system. Thus tonics, cold bathing, and a highly nourishing diet, combined with the bicarbonate of potash and infusion of buchu, constitute our best resources when dealing with cases of endemic hæmaturia. The pathological facts clearly show that in order to effect a cure we must imitate nature herself as closely as we can. We must seek to erect artificial barriers, and thus check the hæmorrhage as much as possible. For this purpose the writer has found the astringent properties of *Arctostaphylos uva ursi* eminently serviceable; small quantities of hyocyanus being usefully combined. Dr. Harley advises 'a persevering use of belladonna and henbane,' under the impression that treatment with these drugs 'will retard the development of the parasite, even if they do not effect its destruction.' The writer entirely disagrees in this view of the case, and he also objects to the employment of medicated injections. He thinks that the employment of diuretics is likewise clearly contra-indicated. Everything that will contribute towards allaying the vesical irritation, is certain to assist the natural process of cure; and, in this view, the administration of buchu-infusion, the enforcing of a liberal diet, and the taking of gentle exercise, will be found amongst the most important curative aids. In bad cases a thorough cure is not likely to be completed until after the lapse of several years. Prophylactically it is essential to remove patients from the localities in which there is every reason to believe they have contracted the disease. In view, also, of preventing infection on the part of others, it is necessary that the water employed for domestic purposes throughout the infected districts, be rendered thoroughly pure by efficient filtration. For further particulars the reader is recommended to consult the general works of Küchenmeister and Leuckart, the writer's introductory treatise on *Entozoa* (p. 197 et seq.); Dr. Harley's three separate memoirs (in the *Transactions of the Royal Med. and Chir. Soc.*, 1864, &c.); and also especially the recent memoir by Dr. Sansino, entitled 'Researches concerning *Bilharzia hæmatobia* in relation to the endemic hæmaturia of Egypt, with a note on a nematoid found in human blood' (*Rend. della R. Accad. delle Scienze*, &c., 1874). See also HÆMATOZOA.

T. S. COBBOLD.

BILIARY CALCULUS. See GALL-STONES.

BILIARY FISTULA.—There are two kinds of biliary fistula:—one, in which a communication exists between the gall-bladder and the surface of the body; the other, in which there is a communication between the gall-bladder and other internal organs. Neither kind is common, but the first is less rare than the other.

In the first variety a tumour forms, sometimes in the place of the gall-bladder, at other times near the umbilicus, in the linea alba or to the left of this line, or in the groin. The tumour, if opened spontaneously or by the surgeon, discharges a quantity of pus, bile, and gall-stones. If the cystic duct

be obliterated, no bile need escape. A suppuration of the gall-bladder, caused by the presence of gall-stones, is the common cause of these fistulae. The prognosis is good. The diagnosis, before the tumour opens, is very difficult. In a case which came under the writer's notice, it was mistaken for an abscess of the liver.

In the second kind of biliary fistula, the gall-bladder may communicate with the duodenum or colon; with an abscess of the liver; with the portal or other abdominal vein, though it must be owned that cases of this kind seem somewhat dubious; or with the urinary bladder, or at least with some part of the urinary tract. Gall-stones are in nearly every case the cause of the fistulous opening.

J. WICKHAM LEGG.

BILIOUS.—This term is used with much vagueness, and in popular language is often employed very incorrectly, though the idea is to associate it with conditions in which an excessive formation of bile is supposed to occur. The chief uses of the word are as follows:—In the first place it is employed to designate a peculiar temperament—the *bilious temperament*. Again, individuals are often said to be *bilious* when they present a sallow or more or less yellowish tint of skin, but especially if they are distinctly jaundiced. *Bilious vomiting* and *diarrhoea* signify respectively the discharge of a quantity of bile, mixed with vomited matters or with loose stools. Certain febrile diseases, attended with yellowness of the skin, are sometimes designated *bilious fever*, and under like circumstances pneumonia has been described as *bilious pneumonia*. Lastly, one of the most frequent applications of the term is to certain so-called *bilious attacks* or *biliousness*, which, however, are commonly merely attacks of acute dyspepsia or migraine. The most prominent symptoms of a supposed *bilious attack* are anorexia, furred tongue, a bitter taste, sickness, constipation, and headache, with a feeling of marked depression and general malaise. Such attacks are most effectually prevented by careful regulation of diet, and the avoidance of exposure to cold, fatigue, and undue mental exertion or anxiety; when they come on, abstinence from food is desirable, with rest in the recumbent posture, and perfect quiet. Alterative aperients and saline effluents may be given, alcoholic stimulants being avoided as far as possible.

FREDERICK T. ROBERTS.

BILIOUS TEMPERAMENT. See TEMPERAMENT.

BITTER ALMONDS, Poisoning by. See PRUSSIC ACID, Poisoning by.

BLACK VOMIT.—Vomited matters may be more or less black in different diseases, but the peculiar *black vomit* is that which occurs in yellow fever (see YELLOW FEVER).—The rejected matters are acid in reaction, and a sediment is deposited of coagulated albumen and disintegrated blood-corpuscles. Ammonia is also present. The black colour of the vomit has been attributed by some writers to altered bile, but there can be no doubt that it is due to its admixture with blood which has undergone certain changes.

BLADDER, Diseases of.—The bladder may

be the seat of the following morbid conditions:—Inflammation, acute or chronic; Abscess; Neuralgia; Atrophy or Hypertrophy; Mechanical Distension, with chronic engorgement and retention of urine, commonly, but erroneously, termed 'Paralysis'; Saccululation; Displacements, such as hernia in the male, or, very rarely, inversion and protrusion in the female; Tumours or Growths, including fibrous, villous, or vascular growths; Epithelioma and Carcinoma; Tubercular Disease; Ulceration, either simple or malignant; and Vesico-vaginal or Vesico-intestinal fistula. The bladder may also be the subject of true paralysis, partial or complete, as the result of injury to the brain or spinal cord, or following disease of those organs.

Only a brief statement respecting the most important of this class of affections need be presented here, in order to facilitate an acquaintance with their diagnosis, since the treatment of almost all of them belongs to the province of the surgeon, and so far only as it consists of medicinal remedies will the subject be considered.

1. **Acute Inflammation—Acute Cystitis.**—The mucous lining of the bladder is the part affected by inflammation—and although after long and severe attacks some morbid action occurs by extension to the muscular coat, or even to the peritoneal covering, these structures are very rarely affected. An acute inflammation of a very severe kind occurs from injuries; from the presence of instruments, foreign bodies, or calculi; and from unrelieved retention of urine. A less severe, somewhat evanescent, but very painful form of cystitis arises from irritants taken internally, as cantharides. A still less severe, but often troublesome form originates by extension from gonorrhoea.

In the first class of cases there are not only severe local symptoms referable to the bladder, but the general system may be gravely affected.

In the second class, of which cantharides-poisoning is the type, the phenomena of very frequent, painful, and spasmodic attempts to eject small quantities of urine which is often bloody, occur within a very short time after absorption of the poison. A common blister is said to produce the affection in some persons. In two cases—the only two the writer has seen—it has followed the application of a blister to a surface already partially denuded of the scarf skin. In one of these a blister was applied to a knee which had been frequently painted with tincture of iodine, and was still slightly sore. In three hours after the application the patient was attacked with exceedingly painful efforts to micturate, which were at times intense. The attack lasted six hours, gradually diminishing in force, and leaving no ill-effects behind. In less than twenty-four hours no trace of the symptoms remained.

In the third form of cystitis, which is the most common, and of which that arising by extension from gonorrhoea may be taken as the type, the usual symptoms are undue frequency of micturition; a necessity to perform the act immediately the want has declared itself, a condition conveniently expressed by the single word 'urgency;' a desire to pass more, accompanied by pain, when all the urine has been voided; and

some dull aching over the pubes; together with a general febrile state of the system, often very slight, but corresponding for the most part with the degree of local inflammation. The urine itself is cloudy, and deposits some light mucus on standing, but is not otherwise apparently altered. Under the microscope abundance of epithelium is visible, as well as some pus-cells, and if the affection is severe, a few blood-corpuscles are also present. It may be remarked here that the presence of a few pus-cells in the urine, a fact to which so many practitioners attribute considerable importance, by no means necessarily deserves to be so regarded. The very slightest attack either of this or of the preceding form of cystitis is certain to be attended by the formation of some quantity, however small, of fully-developed pus-cells.

Very rarely a *false membrane* may be produced on the surface of the mucous membrane of the bladder, and may be thrown off almost entire, leading to the belief that the inner coat has itself been exfoliated. In women this membrane has been voided per urethrum in a condition for examination; in men this cannot occur, because the urethra is too small to admit of it. Now and then examples of the former have been shown at the Pathological Society of London, and one of the latter may be seen, discovered by operation, in the museum of the Royal College of Surgeons of London.

TREATMENT.—In the first form of cystitis, the removal of the exciting cause, if possible, is the chief indication.

The treatment of the second form should consist of very hot bidets or hip-baths, the former being probably preferable as capable of being used at higher temperatures than the latter; together with large doses of the tincture of henbane, say a drachm, with 10 or 15 drops of liquor opii every two hours while pain is severe; 20 minims of liquor potassæ may be given either simultaneously or alternately, in water or in any bland diluent.

The treatment of a well-marked case of the third class consists in absolute rest in the recumbent posture, mild diet, abstinence from all alcoholic stimuli, gentle laxative action of the bowels, and the administration of small doses of alkali. The writer prefers liquor potassæ to all others, frequently repeated; and this may be combined with henbane, or, if micturition is very frequent and painful, with opium or morphia, or with chlorodyne in small doses. Hot hip-baths or bidets, followed by hot linseed-meal poultices or fomentations, give great relief. The patient may drink freely of decoction of triticeum repens, linseed tea, barley water, or similar demulcents. Relief rapidly follows, but care is requisite to avoid relapse, which easily occurs if exercise be taken too soon, if injections for the gonorrhœa be resumed too readily, or if alcoholic stimulants are freely taken.

2. Chronic Inflammation—Chronic Cystitis.—Chronic inflammation of the bladder is separated from the acute form by very distinct characters. It is mostly the result of retained urine from stricture or enlarged prostate; but it may arise from the presence of calculi, or of growths in the bladder; from over-distension, or atony of

its coats; from paralysis after injury or disease affecting a nervous centre; from disease of neighbouring organs; and sometimes from altered urine: it is also met with in certain affections of the kidney. Sometimes this condition is marked by the presence of a large quantity of viscous mucus, often called 'catarrh'; but more commonly this symptom is absent, and the urine contains merely ordinary mucus or mucus-pus, rendering the secretion more or less cloudy and opaque. Perhaps there are some cases in which the inflammation is mainly due to the presence of gout.

SYMPTOMS.—The symptoms of chronic cystitis are increased frequency of micturition and pain, but the latter is by no means necessarily present. The urine is always cloudy, and contains some pus-cells. There is often, but not always, some suprapubic uneasiness. The general health does not suffer unless the affection is prolonged or severe. If important causes, as the presence of stricture, calculus, &c., occasion the chronic cystitis, their specific symptoms will predominate. It is not common to find chronic cystitis as an idiopathic disease, although undoubtedly it occasionally is so; so that the writer has always regarded it as a useful maxim, 'When chronic cystitis is declared to be idiopathic, we may be sure that we have only not yet discovered the real cause.' As a general rule we may be sure that there is inability to empty the bladder, or calculus, stricture, or organic disease of some kind in some part of the urinary tract, when the group of symptoms are present which we denote by the term 'chronic cystitis.' Respecting the well-known glairy mucus, which is deposited so abundantly from the urine in some cases, in elderly people almost invariably, it should be said that it appears only in those whose urine is abnormally retained, through atony of the vesical walls, or in consequence of enlarged prostate, or as the result of accumulation of the bladder, and that medicine has little or no effect upon it.

TREATMENT.—The regular and habitual use of the catheter, and perhaps also injections into the bladder, form the essential mechanical treatment of chronic cystitis in the cases just mentioned. In the few cases in which chronic cystitis is present, and no organic cause, such as those named above, can be discovered—and also as adjuncts to mechanical treatment when those causes do exist—certain medicinal agents are undoubtedly useful: these are buchu, triticeum repens, uva ursi, alchemilla arvensis, pareira brava, and the alkalis potash and soda. Buchu is more useful in subacute and recent chronic cystitis than in cases already of long duration. The patient should take not less than ten ounces of the infusion daily. After this, in similar cases, the decoction of triticeum repens, made by boiling two to four ounces of the prepared underground stem in a pint or a pint and a half of water, of which six ounces should be taken three or four times in the twenty-four hours, is highly useful. For more chronic cases, where the urine is alkaline and deposits much mucus, and perhaps the triple phosphates also, alchemilla, uva ursi, and pareira brava may be very valuable. The alchemilla is administered in infusion, one ounce of the

herb in one pint of boiling water, of which the dose is four to six ounces three times daily; the others according to the directions of the pharmacopœia. These may be taken alone or combined with potash, which in moderate quantities diminishes the natural acidity of the urine before it enters the bladder; the mucous membrane of which, although accustomed to that condition in health, is perhaps sometimes, when inflamed, irritated by urine of even the ordinary acidity. Whether this be so or not, there is no doubt that alkalis do frequently tranquillise an irritable bladder. They are often given in the form of Vichy water, Vals water, or that of Erian, all strong solutions of soda; but on many grounds the salts of potash are preferable. On the other hand, the mineral acids have been largely administered in cases where the urine is alkaline; although there is no reason to believe that the acid has any direct action through the kidneys, or that it is eliminated by those organs. Alkalinity of the urine in chronic cystitis is almost always due to inability of the bladder to empty itself, and the remedy wanted is not medicine but a catheter, at all events to ascertain whether this be the cause or not. A very small quantity of urine retained in the bladder, say one or two ounces, after every act of micturition, suffices in some cases to maintain an alkaline and otherwise unhealthy state of the secretion: while it is equally true that some patients may habitually, and during long periods of time do fail to empty the bladder, always leaving behind from half a pint to a pint, without losing the acidity of the urine. Of course other signs, and notably great frequency of micturition, are present when such is the case.

3. *Neuralgia*.—It is impossible to deny that the bladder may be, like other parts of the body, subject to symptoms which are described as neuralgia, although the occurrence is an extremely rare one. All the writer can say is, that he has occasionally met with cases in which he has not been able to account, by the existence of any lesion, for pain and frequency in micturition, or for difficulty in performing that act, and where these symptoms have been more or less periodic in their appearance. In such instances he has given quinine, and has occasionally found great relief to follow a few doses; more frequently this has not been the case. But now and then the value of the drug has been so marked as to corroborate a belief in the existence of vesical neuralgia. It must be repeated, however, that examples of such phenomena are extremely rare. The writer has also employed arsenic on the same ground. It is invariably necessary to investigate the general health, as well as the habits and diet of the patient. This, perhaps, may be the place for stating that in all chronic and slight deviations from natural and healthy function in the urinary organs, it is essentially necessary to inquire into the state of the digestive organs, to correct by diet and by medicine when necessary any imperfect action on their part, if possible. Constipation alone, when habitual, may produce considerable irritability of the bladder, so also may the unnecessary use of purgatives. A gentle, easy, and daily action of

the bowels, a healthy condition of the primary digestion, the absence of flatulence and distension after food, should be ensured as far as possible in all patients complaining of frequent, difficult, or uneasy micturition; and many such may be completely cured of so-called urinary affections by strict attention to these matters. The writer's strong convictions relative to this fact, grounded on innumerable experiences of its value as an aid in practice, led him nearly twenty years ago to ascertain the great value, for such patients, of Friedrichshall water, now so extensively used; and more than ever he insists on the use of a mild and laxative regimen and diet in their management.

4. Where obstruction to the outflow of urine exists (stricture of the urethra, most forms of enlarged prostate, other tumours, &c.), the muscular walls of the bladder become the seat of *Hypertrophy*, which is a condition of compensation, therefore, and not of disease in or by itself. But such changes in the interlacing muscular fibres existing, *Sacculation* readily occurs, by protrusion of the lining membrane between the bands so produced. On the other hand, most commonly when the prostate is hypertrophied, the bladder becomes gradually distended, its coats become expanded, thinned and weakened, and a certain degree of *Atrophy* takes place. The power of the organ to expel urine is lost or diminished, and micturition being a function of simply mechanical nature, the circumstances of the case demand only a mechanical remedy, viz. the catheter. No medicine can restore power and exercise of function under these circumstances. But atrophy and loss of power may occur from complete or partial loss of nervous influence to the bladder, as in those who are the subjects of paralytic states commencing in the spinal cord or brain. When the paralytic state follows accident causing injury to a nervous centre, the nature of the case is obvious enough. But sometimes the onset and progress of chronic disease in those organs are very slow and insidious; the urinary troubles, as manifested by slowness or difficulty in passing urine, or by urine clouded through inability of the bladder to empty itself, may be the earliest signs of the nervous lesion. On the other hand, impaired gait, and other evidences of central mischief, may be and mostly are earlier phenomena, the derangement in the urinary function appearing at a later stage. For such patients, the habitual use of the catheter is often necessary [always of course when unable to empty the bladder by the natural efforts]; while such constitutional treatment as is indicated by the cerebral or cerebro-spinal lesion present will comprehend that which the bladder demands. It is therefore unnecessary to allude further to that subject in this article. The same remark also applies to those few examples of *Tubercular disease* of the urinary organs, which is always a local expression of a general constitutional state sufficiently considered under its proper head in this work. All other treatment of this malady is local and surgical.

5. *Relative to Tumours*, the varieties of which have already been enumerated, no medical treatment other than that of chronic cystitis is to be thought of.

With almost all affections of the bladder, simple or malignant, ulcerative or associated with fistula, cystitis to some extent and in some form co-exists. It is this which gives rise to the presence of an undus quantity of mucus in the urine; it is often the source of pus, sometimes of blood in small quantity. Thus in all the above-mentioned diseases, some degree of cystitis appears sooner or later. **HENRY THOMPSON.**

BLADDER-WORMS.—Entozoa having the character of cysts or vesicles, and being at the same time more or less transparent. This general term embraces a variety of parasitic forms, such as *Echinococci*, *Cenuri*, and *Cysticercus*, all of which are the larvae of different species of tapeworm. Practically, it is important to know the origin of every kind of human bladder-worm, since the adoption of appropriate hygienic measures may prevent infection by each of the various species. See *ECHINOCOCCUS*, *CYSTICERCUS*, *HYDATIDS*, *MELASLE*, *TENIA*, and *TAPEWORM*. **T. S. COBBOLD**

BLAIN.—A blister, as in the case of chilblain. According to Mason Good, blains are 'orbicular elevations of the cuticle, containing a watery fluid.'

BLEB.—A large vesicle or bulla, containing for the most part a serous fluid, as in pemphigus, erysipelas, or burns and scalds. See *BISTUR*

BLENNORRHOEA, BLENNORRHAGIA (*Βλεννα*, phlegm, and *ῥέω*, I flow; *Βλεννα*, phlegm, and *ῥήγνυμι*, I burst out). These terms are most correctly used to express excessive flow of mucus from any mucous surface. By means of an affix, the locality or nature of the discharge is expressed: e.g., *blennorrhœa oculi, nasalis, urethralis*. More commonly, however, and less accurately, *blennorrhœa* is employed as synonymous with *gonorrhœa* in the male or female.

BLEPHARITIS (*Βλεφαρις*, an eyelid) Inflammation of the eyelids. See *EYE* and its Appendages, Diseases of

BLEPHAROSPASM (*Βλεφασμος*, an eyelid, and *σπασμος*, a spasm). Spasmodic movement or contraction of the eyelids. See *EYE* and its Appendages, Diseases of.

BLINDNESS.—Loss of sight. See *AMAUROSIS*, and *VISION*, Disorders of.

BLISTER.—*SYNON.* Bieb; Bulla; *Fr. Bulle*; *Ger. Blase*.

DEFINITION.—A vesicle of the skin, caused by the separation of the horny cuticle from the rete mucosum by the transudation of serous lymph beneath the former.

ÆTIOLOGY.—Blisters may be idiopathic, as in pemphigus; or symptomatic, as in erysipelas. They are met with under the influence of any cause which depresses the vitality of the integument, as in some forms of prurigo, in chilblain, and in carbuncle; in scalds and burns; and as an effect of powerful irritants, such as cantharides or the aniline salts.

DESCRIPTION.—A blister ranges in size from that of a pea to a turkey's egg; it is more or less convex according to the amount of exudation; and conforms in colour with that of its contents, being sometimes yellow or amber-coloured and transparent, like serum, sometimes opalescent

from the presence of pus, and sometimes red or purple from admixture with blood. The fluid of a blister, generally limpid and free, is sometimes held in the meshes of a delicate network, resulting from the stretching of the connecting cells of the rete mucosum and horny epidermis. This is peculiarly the case in blisters developed under the influence of acute inflammation, and especially in *Dermatitis acilina*. Blisters may be dispersed, or aggregated, or even single, as in *Pemphigus* or *Pompholyx solitarius*.

TREATMENT.—Blisters are essentially æsthetic in their nature, and call for corroborant therapeutical treatment. Locally they should be punctured so as to admit of the gradual escape of their contents, and then dusted over with some absorbent powder, such as oxide of zinc, fuller's earth, or cinchona. **ERASMUS WILSON.**

BLISTERING.—A therapeutic measure which consists in the artificial production of blisters on the skin. See *COUNTER-IRRITATION*.

BLOOD, Abstraction of.—*SYNON.*: Bleeding, Blood-letting. *Fr. La Saignée*; *Ger. Der Aderlass*. — **DEFINITION.**—The withdrawal of blood from the body, either (a) from the general circulation, by arteriotomy or phlebotomy, or (b) locally, by leeches, scarifications, or wet-cupping.

It is to the first two of these methods of abstracting blood that the term 'bleeding,' or 'blood-letting,' has by common usage been restricted.

The topical abstraction of blood by means of leeches, scarifications, and cupping, though often valuable, is of secondary importance. The present article will, therefore, chiefly be devoted to *general bleeding*.

General Bleeding.—This art, practised for centuries more or less universally, has of late years in this country fallen into disfavour. Much discussion has been raised as to the grounds for so great a difference. It has been attributed—(1) to the type of disease having undergone a change, (2) to mere fashion or caprice; (3) to a better knowledge of the nature of disease, teaching us that its processes were of a lowering or depressing character, which were to be overcome, not by the abstraction of blood, but rather by the use of stimulants and support. It is highly probable that several causes have contributed to the undoubted change which has taken place. The year 1830 and subsequent years were marked by the epidemic visitation of cholera and of influenza. These diseases were characterized by extreme depression. If antiphlogistic measures were adopted, they proved failures, and taught the physician that blood-letting was not the universal panacea it was supposed to be. By degrees it ceased to be practised as it used to be. A new generation which knew not the past has sprung up; and, as in all reactionary movements, the practice has become at length as limited as it formerly was universal. It is almost certain that in either extreme there is an evil, and that we may have recourse in certain cases to abstraction of blood with some degree of that success which formerly led to its extensive use, if not its abuse. It will be well to consider the subject at some little length, and under the following heads:—

1. The effect of moderate losses of blood on the healthy economy.

2. The value of bleeding as a remedy in disease, together with the indications for its employment in various affections.

3. The method of performing the operations of opening an artery—arteriotomy; and opening a vein—phlebotomy.

1. **EFFECTS.**—We have first, then, to consider the effect of moderate losses of blood upon the healthy economy. Upon this point we have abundant evidence, for the custom of regularly bleeding healthy people had reached such a point during the earlier half of this century that in country districts it became a practice for adults to be bled as regularly as they went to market. No better testimony regarding the effects of this practice could be adduced than that of Sir James Paget, who, when referring to these customary venesections, says: 'I can regard those as a series of venesections fairly performed for the determination of what is the influence of the removal of blood up to the point of syncope upon a comparatively healthy person. I think I can say surely that not one of these persons suffered harm' To this might be added other and abundant testimony to the harmlessness of venesection on the healthy economy.

2. **INDICATIONS AND USES.**—Concluding, then, that the abstraction of a limited quantity of blood has no deleterious effect upon the healthy organism, we will next set forth the general indications for the use of bleeding in disease, and briefly refer to the various affections in which it may most suitably be employed.

Broadly stated it may be said that bleeding is indicated when there is evidence of marked over-distension either of the arterial or of the venous system. In either case the result will be cardiac distension—in the former case of the left, and in the latter of the right chambers of the heart. In such conditions general bleeding restores the lost equilibrium of the vascular system, and relieves the heart and the other parts concerned in the circulation of the blood.

The arterial system may be in a state of augmented tension from two causes: (1) contraction of the arteries (the smaller vessels) themselves with a diminished amount of blood in the arterial system; and (2) engorgement or distension of the arteries from spasm of the arterioles: both may be regarded as vaso-constrictive neuroses. In the first case there may be engorgement of the venous system and embarrassment of the right heart, calling for abstraction of blood by *venesection*; or visceral fluxion, the skin being pale; and in the second, relative emptiness of the veins with overfulness of the larger arteries, calling for blood-letting by *arteriotomy*.

In the former condition there would be, in *bad-side* language, a *small* hard or wiry pulse, and in the latter a *full* and hard or bounding pulse. In the former the surface of the body may present one of the two following conditions: either the skin is injected and, perhaps, dusky, and this appears to be the case ordinarily; or it is pale and cool, the blood having receded inwards, chiefly to the abdominal viscera. The second condition obtains and is well seen in

cases of uræmic asthma, when the arterial system is turgid almost to bursting, while the veins are comparatively empty. 'Hardness' of the pulse is usually said to be an indication for bleeding, and in certain associations it is so; but it is necessary to discriminate carefully between the 'hardness' due to 'tension' of the sound artery arising from (a) excessive contraction (the small, hard, wiry pulse), and (b) overfulness (the full, bounding pulse) on the one hand; and that due to arterial degeneration with more or less hard deposit in the walls of the vessels, on the other. In doubtful cases inquiry should be made into the state of the brachial artery at the bend of the elbow. This can readily be done by flexing the limb, when, if calcareous degeneration have taken place, the vessel will be thrown into serpentine folds, visible, except in fat people, to the eye, and cord-like and rigid to the touch. The temporal artery is a less safe guide, but neither it nor an arcus senilis should be overlooked in this connexion. A visible and tortuous pulse in a young person may indicate aortic regurgitant disease: the age of the patient must therefore be taken into consideration.

Dilatation of the arterioles would permit of the rapid passage of arterial blood into the veins: under such circumstances, therefore, we should expect the blood issuing from a cut vein to present a more florid appearance than under ordinary conditions. Bleeding here should be undertaken with considerable circumspection, and not be pushed very far, for collapse out of proportion to the amount of blood abstracted might ensue. On the other hand, when there is spasm of the arterioles, and the abstraction of blood is deemed advisable, it would be well to resort to arteriotomy rather than venesection. The best guide here would be the sphygmograph, but, as few persons are yet accustomed to use it, the full, hard, bounding pulse must be relied on when found in association with corroborative symptoms.

Whatever leads to over-engorgement of either side of the heart may render bleeding necessary. If the left side of the heart be over-full, arteriotomy is indicated; if the right, venesection. The object of the withdrawal of blood from the general circulation is the direct relief of the overburdened heart. Whether the right or left chambers be taxed the immediate effect is the same; they are over-distended, and cannot get a grip upon their swollen currents. It is with the embarrassed heart as with other hollow muscular organs—the bladder and uterus. Over-distension paralyzes them by removing the 'points d'appui' essential for the initiation of muscular contraction; the energy may be there, but it cannot be exercised. It is obvious that the amount of blood which it is necessary to withdraw, in order to free the embarrassed organ, must vary considerably in different cases. But it may be safely laid down as a rule that it need rarely exceed a few ounces. Excess in this respect is the evil which formerly existed.

On this subject we may refer to the eminently practical remarks of Sir Thomas Watson, who says: 'I hold it, then, to be certain, that for some special morbid conditions, which inflammation may or may not accompany, general blood-letting, and especially venesection, is a potent and life-

providing remedy, that there are many exigencies for which it is not only safe to employ, but unsafe and unpardonable to withhold it.

He also gives the following judicious advice:—

‘Always it is necessary to consider the age, the sex, the general temperament and condition of the sick person, when we are turning over in our minds the expediency of abstracting blood. The very young, the old, the feeble, the cachectic, do not bear well the loss of much blood. This consideration is not to deter you from bleeding such persons topically when they are attacked by dangerous inflammation, but it especially enforces, in regard to them the golden rule that no more blood should be abstracted than seems absolutely requisite to control the disease.’

The following are some of the affections under which blood-letting would seem to be more or less indicated:—

Pneumonia.—Blood-letting in pneumonia, as in many other inflammations, is most useful in the early stages. It is indicated in healthy patients suffering from uncomplicated acute sthenic pneumonia, if they happen to be seen early enough. It relieves pain, abates fever, and if it does not arrest the disease, it certainly appears to lessen its duration. It may also be called for when there is severe pain and evidence of cardiac embarrassment. It did good, and will still do good, in cases of pneumonia, attended by embarrassment of the circulation, and that in truth is the indication for bleeding in this disease.

Apoplexy.—The same may be said with reference to cerebral apoplexy. The old belief in the importance of ‘letting blood’ in cases of apoplexy was, if possible, stronger than in cases of pneumonia. But here again more accurate clinical and more extended pathological knowledge have taught us to look upon ‘apoplexy’ very differently to our forefathers. Recognising the escape of blood from the bursting of a brittle artery as a common cause of ‘apoplectic fits,’ we see the futility of venesection when the ‘stroke’ or ‘fit’ is due to a lesion of this kind. Nor will bleeding unstop an artery when it is plugged by an embolus, or carry nutriment to the region thus bereft of vital fluid. On the other hand we have learnt to recognise the value of bleeding in another class of cases of so-called ‘apoplexy’—those which are unaccompanied by effusion of blood or lesion of the nervous tissue, but depend on rapidly occurring compression of the nervous centres from sudden or unequal increase in the volume of any portion of the cranial contents; or in certain eclamptic cases from the circulation of blood poisoned by uneliminated urinary excreta. In cases of this description, when the right heart and venous system are engorged, phlebotomy acts well; the stertor will cease, the purple face resumes its natural hue, the clouded intelligence becomes clear, and the impending danger is for the time averted. This has not cured the patient, however. It has only ‘obviated the tendency to death’: it has saved the patient’s life, though he may ultimately die of the disease which afflicts him. Where we meet with evidence of cerebral congestion accompanied by fullness of

the veins, a dusky countenance, and a slow full pulse, bleeding may most usefully be resorted to. In a word, although bleeding will not remove the effused blood in cases of cerebral hæmorrhage, it may sometimes be usefully employed to prevent further escape, when the heart is acting too forcibly; but it is altogether forbidden when that organ is suffused. The pulse at both wrists should be attentively examined before bleeding, in cases of cerebral hæmorrhage, for as a rule it is larger on the paralysed than on the sound side.

Eclampsia.—Indiscriminate bleeding in eclamptic seizures would be a grievous error. It would not relieve, but rather would probably intensify, convulsions of reflex origin, as in certain cases of puerperal convulsions. On the other hand, cases of puerperal convulsions accompanied by great turgescence of the vascular system, whether venous, (as is commonly the case) or arterial, would be immensely benefited by the withdrawal of blood from the general current, either by venesection or by arteriotomy, according to the indication. This treatment may serve to stop the convulsions, and though that may be far from curing the disease, it may, nevertheless, be of the utmost value, for in the first place the fits themselves may kill by their violence or frequent repetition; whilst, secondly, time may be gained for the employment of other measures calculated to relieve the oppressed system, as, for example, purging by hydragogue cathartics, vapour baths, cupping the loins, &c. This gain may be immense, for bleeding may avert impending dissolution. Moreover, permanent good may ensue, inasmuch as bleeding reduces temperature, and in the eclampsia of pregnancy the temperature is usually high. In this it contrasts with pure uræmic convulsions, in which there is lowering of temperature.

Venous Engorgement.—Engorgement of the venous system arising from chronic disease, e.g. pulmonary emphysema or heart-disease, does not call for bleeding, unless the condition be acutely intensified by some intercurrent mischief, such as acute bronchitis, for as the engorgement is slowly produced the organs and structures involved learn to accommodate themselves more or less to the altered conditions. It is only when vascular engorgement suddenly occurs in apparently healthy subjects, or, as stated above, there is acute intensification of a chronic condition, that bleeding is required. Thus, in cases where mediastinal tumours impede the return of blood from the head and upper portion of the body, the condition is ordinarily of such comparatively slow production, that bleeding is seldom urgently called for; and, moreover, it would be of but small service, for the obstruction is irremediable.

The lividity of the face which accompanies all fits should not be confounded with the duskeness due to engorgement of the venous system generally.

Uræmia.—In pure uræmia bleeding is useful; the kidneys being especially in default. For venesection answers a double purpose, by not only relieving the engorged right heart and venous system, but removing from the body a certain amount of poisoned blood—blood that is charged with urinary excreta. Doubtless, it does

good in both ways, but the former is, *quoad* the fits, the more important because more immediate mode of its action. The second effect, that of ridding the body of damaged blood, is obviously available to us when we have to deal with uræmia, occurring in the non-pregnant; and when coma is deepening, the heart labouring, and the vascular system turgid, no remedy is so swift and sure as the lancet.

Plethora.—Blood-letting may be called for in cases of general plethora, whether sthenic or asthenic. In the former condition the vascular system generally seems to be overfull, though the excess is most marked in the arterial system. Arteriotomy, however, is seldom called for, though it might at first sight seem indicated, since venesection usually answers every purpose.

In asthenic plethora, on the other hand, the venous system only is overfilled; the right side of the heart is distended and its action is laboured. Here venesection is sometimes called for, but it should be carefully employed. It is seldom necessary to withdraw more than 6 to 10 ounces of blood, and often a smaller quantity suffices.

Peritonitis.—The relief obtained by bleeding in acute peritonitis rendered venesection a famous remedy in this affection in former times. And there can be no doubt about its efficacy in relieving the pain of peritonitis, as of inflammation of other serous membranes. It may be used when the patient is young and strong, and in that stage of the disease which is accompanied by a small, hard, and wiry pulse—the pulse of a contracted artery, of augmented tension from contraction, not from overfullness. It is worse than useless in the later stages of the disease, when adynamia has set in. But valuable as bleeding may be in certain cases of peritonitis, it rarely happens that it is admissible, for in the great majority of cases inflammation of the peritoneum is secondary to other diseases, and notably to disease of the kidneys. Where peritonitis arises after delivery it is commonly of septicæmic origin, and it is seldom indeed that bleeding is of any avail under these conditions. So that, practically, bleeding is not a remedy which we can often employ in peritonitis. A very high temperature cannot alone be held to be indicative of its use for it so happens that such pyrexia is as a rule present only in septicæmic cases. Some cases of peritonitis, even fatal ones, run their course without any marked elevation of temperature: or indeed without showing any definite symptoms. Probably venesection is most serviceable in traumatic peritonitis, or it may be, when the inflammation is localised, though in that case leeches are more suitable.

Pleurisy.—When pleurisy attacks a young and robust patient, and is accompanied by severe pain, great relief follows blood-letting. The blood should be taken from a vein, and *pleno vivo*. But when, as so often happens, pleurisy is, like peritonitis, secondary to damaged blood-conditions—e.g. Bright's disease—bleeding is often inadmissible. When, as in pleuro-pneumonic cases, pleurisy complicates pneumonia, bleeding may possibly be called for, if there be great pain and oppression of the chest; but it should be most circumspectly used. Local blood-letting is much

to be preferred if bleeding be thought necessary; for general bleeding is usually incompatible with the strength of the patient.

Uræmic Asthma.—In the affection known as uræmic asthma, in which there is spasm of the systemic arterioles, with intense turgidity of the arterial system and engorgement of the left heart, bleeding, in the form of arteriotomy, appears to be clearly indicated.

Spasmodic Bronchial Asthma.—Pure asthma is doubtless often a nervous malady, and bleeding is not a remedy which should ordinarily be employed for its relief. It is only admissible when spasm of the pulmonary vessels, or obstruction to the flow of blood through them from bronchiole-spasm, leads to rapid engorgement of the right heart and venous system. This is the exact converse of uræmic asthma: but the effect in both is impediment to the aëration of the blood. Here the abstraction of a few ounces of blood from a vein may give immense and very prompt relief.

Emphysema.—It is not so, however, in the so-called 'asthmatic attacks,' which chronically emphysematous people are so prone to. Here venesection may be imperatively demanded when an acute attack of bronchitis has, by adding to the already difficult passage of blood through the lungs, excited rapid engorgement of the dilated heart and previously turgid venous system.

Purpural Diseases.—Formerly bleeding was much employed in midwifery practice, and especially in inflammatory affections after delivery. We now recognise that for the most part post-partum affections arise from septic mischief and are of an adynamic type. It is but seldom that we are called upon to bleed in these cases. Nevertheless, now and again, venesection may be called for.

Disorders of Menstruation.—Bleeding is a most valuable remedy in certain menstrual disorders, and especially in the plethora of women at the change of life. Many women suffer distressingly from general vascular disturbance at this period. The flushings, headaches, giddiness, feeling of oppression and other vaso-motor phenomena which they suffer from in association with the cessation of the uterine flow, are immensely relieved by an occasional venesection. No other measure will so quickly and so effectually relieve these symptoms. Some robust, plethoric, amenorrhœic young women require periodical bleeding. The writer has known the abstraction of a few ounces of blood to be speedily followed by the occurrence of the menses, in cases of what may be called congestive amenorrhœia of many months' or even years' duration. It may be well to state in this connexion that in certain pulmonary, intracranial, and other visceral lesions, danger may arise from the augmented arterial tension which for a few days precedes the flow, and that the abstraction of blood may avert hæmorrhage into the damaged organs.

After Operations.—Bleeding is less frequently called for in surgical than in medical practice. It is indicated mainly in the after-treatment of cases which present engorgement of the right heart and venous system, as in some cases of ovariotomy and other operations involving the ab-

nominal or thoracic cavities. A turgid venous system, with a small hard pulse, and a labouring heart—a condition which is often associated with scantiness, amounting almost to suppression, of urine—indicates blood-letting after operations of the kind above referred to.

Shock.—In certain cases of shock the abstraction of a limited amount of blood may be required. This point will be found discussed elsewhere (see Shock).

Fever.—That bleeding will lower the temperature of febrile patients has been known from the earliest times. It is, however, not a remedy to be resorted to for that purpose alone, for, as the most pronounced hyperpyrexia occurs chiefly in association with conditions leading to great depression, blood-letting is under such circumstances as useless as it is dangerous.

Insolation.—There are few disorders in which blood-letting is more successful, when rightly employed, than in sunstroke. It is seldom necessary to take more than a few ounces of blood, and excess should be particularly guarded against, for fear of subsequent collapse. The insensible patient with turgid veins, a tight pulse, and labouring heart, will gain immense and prompt relief from venesection. The extreme pulmonary congestion and over distension of the right heart so often found *post mortem* might probably be prevented by the timely abstraction of a little blood from the venous system. Bleeding is not to be thought of in the syncopeal form.

3. METHODS OF BLEEDING.—The following are the methods of performing the operations of arteriotomy and phlebotomy.

Arteriotomy.—This operation is best performed on the temporal artery. The vessel should be partially cut through by a simple transverse incision, and when a sufficient quantity of blood has been obtained it may then be completely severed, so that, retraction of both ends taking place, the hemorrhage may be arrested. A compress of dry lint should then be applied, and a tight roller-bandage applied over it.

Venesection.—The median basilic vein is the one usually selected for the operation on account of its being most readily found. The brachial artery lies immediately beneath it, and care must be taken to avoid wounding the latter vessel. The median cephalic vein is preferable, but is not so easily found. A vein on the dorsum of the foot or other part of the body may be chosen, but, as a rule, it is not desirable to open the jugular vein, especially on account of the danger of the entrance of air, and other risks.

The steps in the operation on the arm are as follows—First, the limb is to be firmly bound above the elbow by a broad tape or fillet. This should be applied with sufficient tightness to compress, and prevent the return of blood by the veins, but not so as to intercept the current in the artery, and extinguish the pulse. An oblique slit is to be made in the vessel by means of a small lancet, care being taken not to cut too deeply. The spurring blood should be caught in a vessel and measured.

When sufficient blood has been withdrawn, the operator should firmly place a thumb or a finger

on the aperture, and then, on removing compression, place upon the wound a dozel of dry lint, antiseptic dressing, styptic-colloid, or such-like, over which a roller-bandage should be twined a few times like a figure of 8, the cross being over the wound.

Local bleeding.—The object of local bleeding is the relief of congested vessels, and especially those of inflamed parts. Arteries convey more blood to, and veins convey more away from, inflamed parts; so that local bleeding may give great relief and initiate resolution, since absorption does not fully commence until inflammation has ceased.

METHODS OF LOCAL BLEEDING.—Blood may be abstracted topically by leeches, by scarifications, or by wet-cupping.

1. Leeching. An average leech will abstract nearly half an ounce of blood. Leeches are extremely useful in a great variety of affections, since a pretty definite amount of blood can be withdrawn from the affected or adjacent parts, or from more distant parts, through intimacy of the vascular connexion, as in diseases of the eye and ear, and in hepatic diseases, accompanied by obstruction to the flow of blood through the portal system, when the application of leeches to the anus is most valuable.

Care should be taken not to apply leeches to parts over which sufficient compression cannot be made to control the bleeding, should any difficulty arise in arresting it otherwise. Thus, leeches should not be applied over the trachea, especially in children, in whom the error of applying them over the episternal notch is sometimes made. For the same reason the fontanelles should be avoided.

The skin of the part where leeches are to be applied should first be washed, and when they do not bite readily the part may be wetted by a little milk or sugar and milk. A slight prick of a needle, sufficient to draw a speck of blood, will often cause them to bite when refractory.

Should the bleeding continue too long after the leeches fall off, pressure or styptics may be applied. If it is desired to encourage bleeding, fomentations of hot water or linseed poultices are serviceable.

In applying leeches to the cervix uteri the precaution of closing the os by a plug of wool, should not be neglected. When applied within the mouth a leech glass should be used.

2. Scarifying.—Scarifications consist in small cuts of a depth not exceeding the eighth of an inch or less into the tissue whence it is desired to take blood. This mode of topical bleeding is mainly applied to the cervix uteri, to the tongue in acute glossitis, and to the palpebral conjunctiva in certain kinds of conjunctivitis; in the last case only slight incisions are permissible. Deeper punctures are made by some practitioners into the tissue of the cervix uteri, but these are punctures and not mere scarifications.

3. Cupping.—Cupping and the use of the scarificator constituting wet-cupping is an important method of topical blood-abstraction; and as a considerable amount of blood can thus be withdrawn, the general circulation may thereby be

affected. It is ordinarily employed, however, for its local effects.

The method of its performance is as follows:—Cupping-glasses being first put on for a brief time, as for dry-cupping (see CUPPING—*Dry-Cupping*), the operator applies to the part selected a spring scarificator so adjusted as to cut only to the required depth—about an eighth of an inch or less. The cupping-glasses are then re-applied, and the desired number of ounces of blood abstracted. If the glasses be too tightly attached the blood will not flow readily, and unnecessary pain may be caused. After their removal adhesive plaster or dry lint and a bandage should be applied to the part.

Cupping over the loins is extremely useful in renal ischæmia; on the temple or behind the ears in certain cerebral disorders, down the spinal column in inflammation of the spinal cord or meninges; and on the chest in certain pulmonary affections.

ALFRED WILTSHIRE.

BLOOD-DISEASE.—The term *blood-disease* was used by the humoral pathologists as synonymous with *dyscrasia* or *anomalous crasis of the blood*, and expressed the idea that the blood was the seat 'almost without exception' of all general diseases. And, further, since purely local disease was considered to be exceptional, the vast majority of diseases were referred to dyscrasies, and were classed under the head of blood-diseases.

The condition of the blood was considered by the humoralists to depend upon the *crasis*, that is the mixture, of its constituents, and prominent among its constituents were reckoned the *blastemata*, or germinal substances of the different tissues, which exuded through the capillary walls in the process of nutrition. When the blood-crasis was disordered or diseased, a dyscrasia was said to exist, and dyscrasies were held to be in the majority of cases primary; though it was allowed that local anomalies of nutrition might and did occasionally occur, and give rise to secondary dyscrasies. A blood-disease or dyscrasia being established, all morbid changes throughout the body were believed to be but local manifestations of the same. For the purpose, therefore, of a rational classification of diseases, a previous classification had to be made of the dyscrasies. The principal blood-crasis were said to be:—

1. The *fibrin-crasis*; including the *simple fibrin-crasis*, the *croupous crasis*, and the *tuberculo-crasis* as varieties. The local expression of the fibrin crasis was inflammation in some form.

2. The *venous crasis*, in which fibrin was deficient. This included a vast number of special crasis, lying at the foundation of the most diverse diseases—e.g., plethoria, heart-disease, acute exanthemata, rickets, albuminous urine, cholera, acute tuberculosis, lardaceous disease, cancer, acute convulsive diseases, metallic poisoning, &c.

3. The *serous crasis*; associated with anæmia.

4. The *putrid or septic crasis*.

5. Anomalous crasis; such as those of syphilis, gout, &c.

The theory of dyscrasies may be said to have declined since the appearance of Virchow's

Cellular Pathology. Virchow showed that the blood is in every relation a dependent and not an independent fluid, and that the sources from which it is sustained and restored, and the exciting causes of the changes that it may suffer, lie without it and not within it. Substances may enter the blood and affect the corpuscles injuriously; the blood may act as a medium in conveying to the organs noxious substances that have reached it from various sources, or its elements may be imperfectly restored. But never is any affection of the blood itself—any 'dyscrasia'—permanent, unless new influences arise and act upon the blood through some channel or through some organ.

At the present time, while it cannot be said that humoralism is professed by many pathologists, the notion of blood-disease, as generally entertained thirty years ago, still clings to the nomenclature, and pervades some of our pathological doctrines. Diseases that affect the whole economy—syphilis, tuberculosis, gout, and cancer—are frequently described as 'constitutional,' or 'blood-diseases,' and that whether their general manifestations are secondary to local disease, as in syphilis and cancer, or are referable to inheritance. While the *morbid conditions* of the blood are real and numerous, 'blood-diseases,' so called, are but abstractions, and, as such, a fruitful source of confusion and useless discussion. It is desirable that the term *blood disease* should be abandoned, and that the expression *morbid conditions of the blood* should be applied to the pathological states of the vital fluid, which can be distinctly demonstrated by physical, chemical, or histological examination.

J. MITCHELL BRUCE.

BLOOD, Morbid Conditions of.—The characters, composition, and functions of the blood in health are sufficiently familiar, and do not require to be described here. But certain facts connected with the physiology of this fluid have a special bearing upon its pathology, and must be briefly considered before its morbid states can be profitably discussed.

A. Physiology of the Blood.—The *Red Corpuscles* of the blood consist of two portions—a colourless, sponge-like matrix, and a coloured substance of complex composition, which occupies the interstices of the former and accurately fills them. The matrix is regarded as possessing chiefly physical properties, while its contents constitute the active part of the corpuscle, and consist of hæmoglobin. The *source* of the red corpuscles is of the greatest pathological importance. In the embryo the blood and blood-vessels are developed from the same elements, and thus the two structures in their physiological aspect are essentially inseparable. In fully-developed blood the source of the red corpuscle is obscure; but there can be no reasonable doubt that it originates in the colourless corpuscle, and more remotely in the lymphatic glands, the spleen, and the medulla of bones; and that light is of the greatest importance in the formation of hæmoglobin. With respect to the properties and function of the red corpuscle, it is to be noted that the ultimate elements of hæmoglobin are carbon, nitrogen, hydrogen, oxygen, sulphur, and iron,

—the last of these probably being the cause of its red colour. Hemoglobin is soluble in water, forming a lake liquid from which fine crystals may be obtained, and which may be variously decomposed, giving rise to other 'blood crystals'. Most important of all its properties, hemoglobin combines with certain gases to form definite chemical compounds,—with O to form oxyhemoglobin, with CO to form carbonic-oxide-hemoglobin, and with N_2O to form nitrous-oxide-hemoglobin. These compounds, and especially the oxyhemoglobin, are exceedingly unstable, being reduced even under very feeble influences to hemoglobin and their other constituents respectively. Alternate oxidation of hemoglobin and deoxidation of oxyhemoglobin are constantly going on within the red corpuscles of the circulating blood; and the two changes, occurring in the pulmonary and systemic capillaries respectively, constitute the first great function of the blood—its oxygenating or respiratory function. The volume of oxygen in arterial blood is 16.9 per cent, and in venous blood 5.96 per cent. It must be clearly understood that disorders connected with the red corpuscles or respiratory elements of the body, whether in amount, composition, or circulation, directly affect the oxidation-processes only. Besides its origin and its function, there is a third relation of the red corpuscle to the organism—namely that of its *products*. These are eliminated by the ordinary channels, the salts, which are chiefly salts of potash, being excreted by the kidneys, and the coloured material furnishing the pigments of the bile and urine.

The *White or Colourless Corpuscles* of the blood, also called *Leucocytes*, are chiefly derived from the corpuscles of the lymph, and the cells of the lymphatic glands and allied organs, which they closely resemble. By escaping through the walls of the blood-vessels, they become identical with the wandering-cells of tissues and with pus-corpuscles,—from which they are indistinguishable except by locality. Such is the origin, and such are some of the functions of the white corpuscles, and its occasional development into the red corpuscle has been already mentioned. It might, therefore, be expected that morbid states of the leucocytes would be associated with disorder of the lymphatic structures and connective tissues, of the red corpuscles, and of the blood-vessels, and this will presently be shown to be the case. The proportion of white corpuscles in the blood is subject to physiological increase, without becoming excessive, as after meals, during periods of growth and development, and in menstruation and pregnancy. This state is called *Physiological Leucocytosis* (Virchow), and signifies lymph-glandular excitement.

Plasma.—The physiological relations of the plasma to the organism are extremely complex; and disturbance of these relations furnishes many of the symptoms of disorder of the blood. Its mature *function* is essentially one of nutrition—it supplies the tissues with oxidisable material for development, growth, support, secretion, and the liberation of force. The *source* of the plasma is equally extensive. It derives its principal constituents from the alimentary canal through the absorbent glands and liver; while other impor-

tant albuminous substances are being constantly supplied from the tissues generally, through the lymphatic system. Lastly, the *products* of the plasma, such as carbonic acid, urea, and water, are discharged by the regular excretory channels. Thus the condition of the plasma is found to be most intimately associated with that of the organs and tissues generally, whether as regards its origin, its mature function, or its products; and it will therefore be affected by disorder or disease of every organ, whether alimentary, sanguiferous, or excretory, and of all the tissues.

Coagulation of the Blood: Fibrin.—Under certain circumstances, especially after removal from the body, the blood coagulates, and fibrin separates more or less completely from the other constituents. This change is now believed to be due to the action of three bodies contained in the plasma—two fibrin-generators, named respectively fibrinogen and fibrinoplastic substance, albuminous in nature; and the third a ferment. The *amount* of fibrin produced varies not only with the amount of these bodies, but with the amount of salts, with the degree of alkalinity and of heat, and with other influences; and these variations are subject to no law at present known. The *rapidity* of the process depends upon (1) the amount of ferment; (2) its increased activity by agitation of the blood and by elevation of temperature; and (3) the increased number of points of contact (so-called 'catalytic' action) by the presence of red corpuscles, hemoglobin, choleol, &c. It thus appears that the expressions 'amount of fibrin' and 'rapidity of coagulation,' however important as facts, do not afford any definite indication of the state of the blood, as has been generally believed hitherto. Three essential factors, and a large number of accidental influences, share in the process; they may do so in very various proportions and degrees; they do not vary together, the amount of fibrin is not in proportion to any one of them, and after coagulation is complete, portions of all the factors probably remain uncombined. The part played by the red corpuscles in coagulation is a double one—(1) the corpuscles, as 'points of contact,' greatly increase the rapidity of coagulation; and (2) they supply oxygen, which appears to be indispensable to the process. The leucocytes probably produce the ferment.

B. PATHOLOGY OF THE BLOOD.—The morbid states of the blood will now be considered in the following order:—1. Changes in quantity, and the effects of such changes upon the composition of the vital fluid. 2. Morbid conditions of the red corpuscles. 3. Changes in colour. 4. Melanæmia. 5. Morbid states of the white corpuscles. 6. The pathology of the blood-plasma; and of the process of coagulation. 7. The presence of foreign materials in the blood, including poisons and infective substances. 8. Organæmia.

1. Changes in Quantity of the Blood.—Alterations in the total amount of blood in the body are perhaps never simple, but always associated with alterations in quality.

a. Polyhæmia, or excess of blood in the body generally, may be the result either of excessive ingestion of the elements of blood; of the accu-

mulation of the same by the suppression of habitual hemorrhages or fluxes; of the loss or obsolescence of a part of the body, such as a limb or a lung; or of insufficient exercise. It cannot be said, however, that polyhæmia has ever been demonstrated by exact investigation, inasmuch as the total amount of blood in the body is still uncertain, and the physiological limits in this respect are very wide. Polyhæmia is believed to be present in *plethora*, along with relative excess of the solids, and especially of the red corpuscles (see *PLETHORA*).

b. Oligæmia or deficiency of the total amount of blood is, on the contrary, an exceedingly frequent change, and constitutes the simplest form of *anæmia*. It is, however, probably never pure, inasmuch as alterations in quality appear to be inseparably associated with it; and the terms *hydræmia* and *spanæmia* have accordingly been used as synonymous with the preceding. The manner in which diminution in quantity gives rise to alteration in quality must be considered here.

When hæmorrhage occurs to any amount, and the whole quantity of blood in the vessels is reduced, the pressure falls, and absorption of the parenchymatous plasma rapidly follows; by which, along with vaso-motor stimulation, the physical relations are restored. If the loss of blood has been moderate, the only change in its composition may be considered to be *oligocythæmia*, or diminution of the red corpuscles, which alone of all the constituents of the blood cannot be rapidly restored. If the hæmorrhage has been more serious, the fluid absorbed into the circulation from the tissues, from the suppressed secretions, and from the alimentary canal, consists of water in ever-increasing excess, which carries with it an amount of salts equal to one-ninth the loss in albuminous substances. The morbid state of the blood is now beyond oligocythæmia; there is deficiency of albuminous constituents, or *hypalbuminosis*, and the condition correctly called *anæmia* is the result. The total quantity of blood probably remains for some time below the normal. A similar impairment of the quantity, and therewith of the quality of the blood, may be slowly developed by repeated small hæmorrhages, or by any cause whatever that impoverishes the blood, whether of the nature of waste or of want. The condition which results closely resembles that just described in the acute form—oligæmia with oligocythæmia and hypalbuminosis: the same is known clinically as *anæmia* (see *ANÆMIA*).

As a *therapeutic measure* oligæmia may be desirable. It may be induced either (1) by direct abstraction of blood, or (2) by gradual impoverishment of the blood, and reduction of the intra-vascular pressure.

2. Morbid Conditions of the Red Corpuscles.—The pathology of the red corpuscles is still imperfectly understood. The following comprise the most important changes connected with them so far as they are known.

a. Polycythæmia.—Increase in number of the red corpuscles is never considerable, being generally transitory and within physiological limits; for example, in the newly-born, and after meals. It has already been mentioned as associated

with polyhæmia in *plethora*. In the *algid stage* of cholera the red corpuscles are relatively in excess.

b. Oligocythæmia.—Diminution in number of the red corpuscles is, on the contrary, of very frequent occurrence, and of the greatest pathological importance. Microscopically the number of red corpuscles in a given visible area of blood is diminished; and chemically the amount of hæmoglobin in a given volume of blood may fall from 15 even as low as 5 per cent. The principal circumstances under which oligocythæmia occurs are—(1) in *anæmia*, or diminution in the amount of blood as a whole, from any cause, whether rapid or protracted, especially as the result of fever, the red corpuscles suffering early, seriously, and persistently, as compared with the other constituents; (2) in *leucocythæmia*—the development of the red corpuscles being interrupted; (3) in *hypalbuminosis*, where the red corpuscles like other elements suffer from want of albuminous material; and (4) in *chlorosis*. See *HÆMAGTOMETR*.

c. Oligochromæmia.—Deficiency of the red corpuscles in hæmoglobin has been described by this name, and is a morbid condition of the greatest possible interest, inasmuch as it is one of the essential alterations of the blood in *chlorosis*. When the individual red corpuscle contains less hæmoglobin than normal, it is said to present a pale appearance to the eye. A more trustworthy method of determining the richness of the red corpuscles in hæmoglobin, is by means of the hæmoglobinometer (see *HÆMOGLOBINOMETER*). Or we may compare the amount of hæmoglobin in a given weight of blood with the number of red corpuscles in a given microscopical area. When the former is small in proportion to the latter, the defect must lie in the individual corpuscle, and this may be so great that the proportion of hæmoglobin falls, as in some cases of *chlorosis*, to 25 per cent. of the normal. See *CHLOROSIS*.

d. Aglobulism.—The effects of the two conditions of blood just described, namely, oligocythæmia and oligochromæmia, may be discussed together under the head of *aglobulism*, or deficiency of the blood in hæmoglobin. Want of the oxygenating substance of the organism gives rise to symptoms at once extremely various, and of the most serious import. Every vital process, whether developmental, plastic, secretory, dynamic, or nutritive, is absolutely dependent on a free and immediate supply of oxygen. All of these processes, therefore, will suffer in *aglobulism*. The respiratory and circulatory movements are accelerated. The complex processes of alimentation and secretion are performed imperfectly, and the results are dyspepsia, constipation, and disordered sanguification—which intensify the abnormal blood-state. Muscular contraction is feeble, and cannot be sustained. Psychical force is weak, and dullness, sleepiness, pains, and other symptoms indicate imperfect oxidation within the nervous system. Bodily growth and development—as of the sexual organs, for example—remain incomplete, and puberty is deferred. Nutrition everywhere suffers, the materials being insufficiently oxidised; and substances 'intermediate' to albumen on the one hand, and carbonic acid, water, and urea on

the other hand, are formed, especially oils. Thus the organs and the connective tissues become loaded with fat and enlarged, instead of suffering atrophy, as they do when the blood-plasma is deficient. Finally the excretions are disturbed, and the subject of aglobulism presents derangement of the colouring matters of the bile and urine, which are derived from hemoglobin.

Histological changes.—Alterations in the *size, outline, and consistency* of the red corpuscle have been frequently recorded, but such accounts are incomplete, and no successful attempt has yet been made to connect any of these changes with morbid processes in the tissues. In severe fevers, such as typhus, and in some rapid malignant diseases, the red corpuscles appear peculiarly soft, their outline being less resistant and sharp, and the bodies running together into irregular heaps, instead of into *rouleaux* with well-defined lines of contact between the elements. In another class of cases the corpuscles appear small and cremated or like the 'thorn-apple.' *Macrocythemia* and *Microcythemia* have also been described as temporary and variable conditions, in which the red corpuscles are abnormally large and abnormally small respectively. *Transitional cells* between the white and the red corpuscle are unusually numerous in some cases of leukaemia.

3. *Changes in Colour.*—The colour of the blood is chiefly due to the red corpuscles, and alterations from the normal in this direction will be best considered in this place, although the white corpuscles and the plasma may also affect the colour, as will be presently shown.

a. The chief determining cause of the colour of the blood is the chemical condition of the hemoglobin. When this is united with oxygen, in the arteries, the blood is *scarlet*, as deoxidation advances, this colour passes into a *purple*, and finally becomes *black or venous*. The dark colour is directly due to absence of oxygen. The purest example of this change is seen in asphyxia, where oxygen is excluded from the blood, but it also occurs as the result of the action of certain injurious influences upon the corpuscle itself, such as extreme heat, or poisoning by phosphorus, prussic acid, and other toxic agents. If the change proceed no farther, the scarlet colour may still be restored by oxidation. This blackness of the blood is generally associated with imperfect coagulation or even a state of fluidity (*see Fibrin*).

b. *Paleness* of the blood is observed in oligæmia and oligocythæmia, and is due to deficiency of the hemoglobin.

c. The blood may be not only pale, but present streaks of a *puriform* character, even as it flows from the living vessels, as in leucocythæmia. The same blood will settle on standing into three layers—of plasma superiorly, loosely coagulated or not; of white corpuscles in the middle—a pus-like layer; and of red corpuscles at the bottom.

d. The *milky* appearance of chylous blood will be described under the head of *Blood-Plasma*.

e. *Lake blood.* The remarkable change in the blood in which it becomes lake or transparent, is frequently observed as a further stage of that first described above; but it may occur under other circumstances than deoxidation, and is of the very gravest significance, inasmuch as

it indicates complete and hopeless destruction of the red corpuscles. Lake blood is no longer opaque, but transparent; the hemoglobin has left the corpuscles and is dissolved in the plasma. The change can be effected experimentally by the addition to blood of water, chloroform, the bile-acids, or other solvents; and it is probable that some of the cases of rapid death after enormous draughts of water, and the destruction of red corpuscles that is believed to occur in jaundice, may be accounted for in this way. But the most important cause of 'solution' of the red corpuscles is complete deoxidation of the hemoglobin, which is followed by its diffusion in the plasma. Thus drawn blood is rendered lake by the addition of sulphide of ammonium, phosphorus, phosphoric acid, or iron-salts; and the same effect is produced by the intravenous injection of salts of the bile-acids. This being so, it might be expected that blood would assume the lake appearance when exposed to the prolonged action of the causes that render it black; and recent observations seem to indicate that such is the case. In a number of diseases which are attended with the accumulation of oxidisable substances in the circulation, the blood has been described as 'fluid,' 'clarot,' or 'cherry-coloured,' 'clear,' and 'staining the tissues,'—but apparently without more exact observations on the colour of the living plasma. Such diseases are high fevers, hyperpyrexia, insolation, and poisoning by malarial, phosphorus, and perhaps other agents. The effect of some of these influences is obviously to produce an excessive amount of oxidisable material in the blood, while the others may lead to the same result by reducing the oxygenating capacity of the corpuscles. Persons dying under such circumstances present great lividity, from the black or venous condition of their blood; death occurs with symptoms indicative of want of oxygen, as if so much of the hemoglobin had been diffused through the plasma; and *post mortem* the vessels are found stained with the solution, the tissues are soaked with fluid lake blood, and decomposition is early and rapid. The 'fluidity' of, or absence of clot in such blood will be presently accounted for under *Fibrin*. That a similar solution or destruction of the red corpuscles may occur in all cases of fever, but in a much less degree, is supported by several facts:—(1) the increased discharge of potash-salts in fever; (2) a similar increase of the colouring matter of the urine; and (3) the anæmia that is found at the termination of the process.

f. Other alterations in colour may occur in the blood. The blood is *light-red* after poisoning by carbonic oxide, and remains so after exposure. It is *chocolate coloured* after poisoning by the nitrites such as nitrite of amyl; and other hues have been recorded.

4. *Melanæmia.*—In relation with the pigment-bearing element of the blood may be mentioned a morbid condition which has been described under the name of melanæmia. In it there are found in the blood black and brown pigment-particles and flakes, free or contained in cells of various shapes. This state is especially associated with two others, namely, malaria and an enlarged deeply-pigmented condition of the

spleen; and it is highly probable that the pigment-particles are produced by the fever, and find their way from the spleen into the blood. They are thus deposited in the liver and other organs, and give rise to symptoms of visceral disturbance during life, and to the peculiar slaty or grey discolouration that is found *post mortem*. It has been said that in melanotic cancer pigmented cells have been found in the living blood.

6. Morbid Conditions of the White Corpuscles.—The white corpuscles of the blood may undergo certain morbid changes both in number and appearance.

a. The most remarkable of these is *increase* in numbers, which may advance to such a degree that the white corpuscles become as numerous as the red. This condition is known as *leucocythæmia* or *leukæmia* (see *LEUCOCYTHÆMIA*). Short of this, however, the proportion of white corpuscles in the blood may be appreciably increased, and to this minor condition the name of *leucocytosis* has been applied. Leucocytosis, according to Virchow, accompanies, almost unexceptionally, every case of lymphatic excitement, such as inflammation, and tubercular scrofulous, or cancerous enlargement or swelling of the glands and allied structures—Peyer's glands, the solitary follicles, the spleen, and the tonsils. Leucocytosis is distinguished from leucocythæmia by its very moderate degree, by its evanescent course; by the absence of deficiency of the red corpuscles; and by the accompanying symptoms. Leucocytosis may be appreciated even by the naked eye in the clot of drawn blood, by the presence of an irregular 'lymphatic layer'—*crusta lymphatica*, consisting of collections of white corpuscles between the red clot and the buffy coat which so frequently occurs along with it.

b. A *diminution* in the number of white corpuscles occurs in chlorosis, and, it is said, in influenza, especially during the paroxysm of fever.

c. With regard to the *structure* of the individual white corpuscles, the proportion of uninuclear or young cells, and of multinuclear or aged cells may be disturbed both in leucocytosis and leucocythæmia; while corpuscles may be found containing granules of various kinds, especially pigment-particles, bacteria, micrococci, and other structures.

6. Morbid Conditions of the Blood-plasma.

—(1) **WATER.**—The limits of the physiological variations in the amount of water in the blood are very wide.

a. *Diminution* of water in the blood is observed in various degrees. It is moderate and transitory as the result of stimulation of the kidneys, skin, or bowels, but the normal proportion is speedily restored by absorption. This condition is found after severe purgation, sweating, diarrhoea, or dysentery; and its production is the rationale of several of the methods adopted for the relief of dropsy. If the drain of water continue, or if the supply fail, the anhydric condition of blood increases, so that the fluid appears black, thick, and tarry. Such is the state of the blood in the algid stage of cholera; the specific gravity of the serum rising as high as 1.080, accompanied by a comparative excess of salts, albumen, and urea. The chief symptoms of great deficiency of water in the blood are intense thirst; a shrivelled shrunken

aspect of the body generally; coldness and lividity of the extremities; muscular pains; and suppression of the excretions—phenomena directly referable to loss of water, retardation of the circulation, and interference with the function of the red corpuscles.

b. Excess.—*Hydræmia.*—Reference has been already made under the head of oligæmia to the anæmia or hydræmia that follows it. Excess of water in the blood is perhaps never absolute, and the change may therefore be regarded with equal accuracy and greater convenience as deficiency of solids.

(2) **ALBUMINOUS CONSTITUENTS.**—On reviewing what has already been said under the head of Coagulation and Fibrin, the reader will observe that 'amount of fibrin,' and other expressions connected with the albuminous constituents, must be regarded at present as comparatively meaningless, in the light of our knowledge of the process of coagulation. Inasmuch, therefore, as little value can now be attached to the analyses of fibrin that have been made in different diseases, it follows that the estimates of the albuminous substances left after coagulation—that is, of the albumins of the serum, must also be rejected. But the total amount of albumins in the blood may be easily ascertained, and this is subject to extensive variations. The balance between the albuminous substances, which enter the blood from the alimentary tract and the lymphatic system, on the one hand, and the products of their transformation by the tissues, on the other, is represented by the albumins of the blood. These will increase accordingly when the supply is excessive, or the consumption small, and will decrease under opposite circumstances.

a. Hyperalbuminosis is the name given to excess of albumins in the blood. The amount has been found notably increased when the activity of the tissues is abnormally heightened, as for example in inflammatory diseases (acute rheumatism, tonsillitis, pneumonia, and pleurisy); and when fibrinogen, which is the product of this increased activity, is poured abundantly into the blood. The amount of albuminous fluid produced in an inflamed part, whether it appears as a catarrh, an infiltration, an exudation, or an effusion, is very great, and may be enormous; and, under favourable circumstances, this and much that cannot be so easily appreciated is carried into the blood, the lymphatic structures swelling *en route*. Hyperalbuminosis as a result of diminished consumption probably does not exist; for the effect of an insufficient supply of oxygen to the albumins—(want of exercise or over-feeding)—is not the accumulation of these in the blood, but the formation of 'lower' products, such as uric acid and its allies, and the deposit of fat. Relative hyperalbuminosis is a necessary but transient effect of cholera and other severe watery fluxes.

b. Hypalbuminosis, or deficiency of albumins in the blood, occurs under exactly opposite circumstances from the preceding,—whether the ingestion of albumins from the alimentary tract and the tissues be comparatively small, or the consumption excessive. Inanition, therefore, on the one hand, and its multitude of causes, are associated with such poverty of blood; and so, on

the other hand, are loss of blood, profuse discharges of albuminous fluids, morbid growths, and other sources of waste, as well as excessive demands of growth and development. The albumins of the plasma may fall under these circumstances from 80 to 37 parts in 1,000. Such hypalbuminosis is, however, never simple: the blood cannot be deficient in albuminous substances and otherwise normal, for, as we have already shown, loss of albumen is always followed by absorption of water and salts from the tissues in definite proportions, and anemia is the result. The red corpuscles suffer at the same time, for their nutritive speedily fails in hypalbuminosis, and aglobulism ensues. Hypalbuminosis is thus a serious disease of the blood. The relations of these conditions to each other and to oligæmia are even more complicated clinically than they are pathologically, and in this relation the whole of them are most conveniently discussed under the comprehensive head of anemia (*see ANÆMIA*).

(3) CLOT, FIBRIN. However uncertain as a measure of any particular constituent in the blood, the amount of clot or fibrin demands a brief notice as a matter of fact.

a. Abundant clot has been considered as indicating an excess of fibrin in the blood or *hyperinosis*, the proportion being stated to rise as high as 1.0 instead of 0.2 per cent. Acute rheumatism, cellulitis, pneumonia, and pleurisy are the diseases in which hyperinosis is most marked, but it also occurs in pregnancy. The two principal conditions of its occurrence appear to be—(1) Increased activity of the tissues—including inflammation, and (2) Free and abundant communication of these tissues with the blood through the lymphatic system.

b. Deficiency, looseness, or absence of clot—'Fluid blood.'—A small loose clot is frequently observed, as for example in typhoid states, or in chronic wasting diseases attended with loss of blood, and has been described as indicating *hypinosis* or deficiency of fibrin. When the condition is extreme, the clot may be absolutely wanting, as in certain cases of anemia the blood then separates on standing into three layers—an upper, consisting of clear liquid, a middle, puriform, of white corpuscles, and a lower, red, of red corpuscles. In another and larger group of cases, non-coagulating or fluid blood is at the same time of an intensely dark colour or even black and is commonly described as 'black.' The circumstances under which this condition of blood occurs, and the cause of the remarkable colour have been already noticed; and it remains to account only for the fluidity. The profound alteration of the red corpuscles, the want of oxygen, the interference with the production of the ferment, and the changes in the fibrinogen and fibrinoplastic substances—one and all combine to prevent coagulation.

c. Buffy coat. Another phenomenon connected with coagulation, from which erroneous and even dangerous conclusions have been drawn, is the so-called *buffy coat*. The process of coagulation is generally sufficiently slow to allow of the gravitation of some of the red corpuscles from the surface of the blood; and the corresponding part of the clot is accordingly paler. When the

pale layer is unusually large it is known as the *buffy coat* or *crusta phlogistica*: it may be seen in the blood in pregnancy, inflammatory fevers, hyperinosis, and oligocythæmia. When these cases are analysed, it is found that the conditions favourable to the formation of the *buffy coat* are probably all more or less connected with the red corpuscles, namely—(1) increased specific-gravity of the red corpuscles, as in oligocythæmia and hydræmia—allowing more rapid sinking; (2) interference with the catalytic action of the hæmoglobin, which is so powerful in determining the rapidity of coagulation, as in fevers and oligocythæmia; and (3) want of oxygen, corresponding to the amount and condition of the hæmoglobin, as in the same diseases. One and all of these states render the process of coagulation slow compared with the descent of the red corpuscles; and the *buffy coat* is the result. It thus appears that the *buffy coat* is no indication whatever of excess of fibrin-generators, or of the opposite, and that it is found under the most diverse conditions of blood.

(4) SALTS.—The amount of positive knowledge concerning morbid alterations of the salts of the blood is but small. It is to be observed that the salts of the plasma have chiefly sodium as their base, while potassium-salts mostly reside in the corpuscles.

a. Diminution.—In febrile diseases there is an increased discharge of compounds of both bases, but at different periods, the potassium-salts appearing in excess in the excretions until the crisis is past, and the sodium-salts during desquescence. At both periods, it may be considered certain that the blood is the chief source of the salts excreted, and that it is accordingly deficient in these constituents.

b. Excess.—On the other hand, the salts of the plasma are relatively in excess in hypalbuminosis, replacing, in the proportion already stated, the lost albumen. The effect on the salts of the blood of such drains as occur in cholera has been variously stated, some authorities declaring that it is an increase, others a diminution.

c. Reaction.—The alkalinity of the blood is said to be diminished in gout, cholera, and osteomalacia.

(5) FATS.—The normal increase of fats in the plasma that occurs after meals may be exaggerated by a diet rich in oil, and it is said, in chronic drunkards and in persons disposed to obesity. When this increase is so great that the serum presents a milky appearance the blood has been called *chylous*. A cream-like scum forms on the surface of the serum; and the milky appearance is found microscopically to be due to the presence of fine granules and oil-globules. A marked increase of fatty matters in the blood has been found in some cases of chyluria. Fat may also appear in the blood as a foreign body, by the escape of marrow into the circulation in fracture of bones—and that in such quantity as to cause fatal capillary embolism.

(6) CARBONIC ACID, which exists in arterial blood in the proportion of 30 per cent., and in venous blood of 3½ per cent., by volume, may accumulate within the circulation either by increased formation or by retention. Although associated with asphyxia, this increase of carbonic acid is

probably not the cause either of the symptoms of that condition, or of the dark colour of the blood that accompanies it.

(7) **OTHER CONSTITUENTS.**—Amongst the most important of the other constituents of the blood, the following are to be noticed:—

a. *Urea*, which exists in normal blood to the amount of 1·8 parts in 10,000, may increase in uræmia by two or three times. There is still much uncertainty, however, on this subject (*see* URÆMIA). Disense of the urinary organs, which interferes with the elimination of urea and allied products from the blood, is the usual cause of uræmia; but excessive tissue-change, as in fever and inordinate muscular exercise, has also the same effect.

b. *Uric acid*, found in normal blood in minute traces, is increased (as urate of soda) in all cases of gout, and may amount, according to Dr Garrud, even to 0·175 parts in 10,000. Its presence is easily demonstrated by the thread-experiment (*see* GOUT). Uric acid is also increased in leukaemia and chlorosis—probably from the imperfect oxidation associated with the condition of the red corpuscles.

c. *Leucum*, *tyrosin*, *hippuric acid*, *sarcin*, and other allied complex compounds, have been frequently found in the blood in small quantities, and the same may be said of *oxalic* and *lactic acids*, and of *acetone*.

d. *Bile*.—Certain of the constituents of the bile may occur in the plasma. The most obvious of these are the *bile-pigments*—*bilirubin* and *biliverdin*, which either by direct formation in the blood from the hæmoglobin, or more frequently by absorption from the liver, accumulate within the circulation, and by their deposit give rise to the colour of the tissues in jaundice. The *bile-acids*—*glycocholic* and *taurocholic acids*—are also under certain circumstances absorbed into the blood where they may be detected with difficulty. They have a destructive effect upon the red corpuscles, and act further as a powerful poison to the tissues, causing the excessively severe symptoms that may occur in hepatogenous jaundice. *Cholesterin* is credited by some pathologists with being the cause of the same symptoms, and it has been found in the blood in increased proportion in some cases of severe jaundice.

e. *Sugar*.—The sugar of the blood is increased in diabetes, in some cases reaching 0·3 to 0·5 per cent.

7. **Extraneous Matters in the Blood.**—Besides its normal constituents and their products, the blood may occasionally contain certain matters entirely foreign to it such as the numerous poisons which act either directly upon the corpuscles, or remotely upon the organism. These, entering the circulation before they exert their specific effect, are in many instances readily discovered by analysis. The acid compounds of hydrogen with sulphur, phosphorus, arsenic, and antimony, respectively, act as blood-poisons by depriving the oxyhæmoglobin of its oxygen; while carbonic oxide and nitrous oxide unite with the hæmoglobin, and expel the oxygen from the blood. It is a matter of speculation whether other so-called poisons, the nature of which is still obscure, do not enter the blood and there exert their primary effect, such as the contagium of acute

specific fevers and other infectious disorders. Similar infective matters, produced in the tissues of the body itself, are believed to be absorbed in septicæmia, pyæmia and other allied diseases, and numerous observations support the further belief that the presence of *bacteria* is intimately associated therewith. A somewhat similar infection may occur in malignant disease, the juices being mixed with the blood-plasma, but in some instances the process may be different, namely by means of cells. We cannot expect to detect these cells in the blood *in transitu*. The same remark applies to emboli,* of whatever nature and to blood-crystals.

8. **Organisms.**—The blood may contain a variety of living organisms, either foreign or peculiar to itself; the latter being called *hematozoa*. *See* HEMATOZOA, CHYTRIA, and KARYOKIN ETTER; also BACTERIA, FILARIA SANGUINIS-HOMINIS, MICROCOCCI, SPIRILLUM, and ZYME. J. MITCHELL BAILEY.

BLOOD. Transfusion of. *See* TRANSFUSION.

BLOOD-WORMS.—This term is of general application. It refers to all kinds of Entozoa living in the blood. *See* HEMATOZOA.

BLUE DISEASE. A condition in which the most prominent symptom is a peculiar discolouration of the skin and mucous membranes, due to the circulation of dark blood in the vessels. *See* CYANOSIS, and HEART, Malformations of.

BOILS.—SYNON.: Furuncles; Fr. *Furoncle*; Ger. *Furunkel*.

DEFINITION.—Gangrenous inflammation of the skin, forming small painful swellings, and ending by expulsion of the necrosed centre or 'core'. The inflammation begins in the glandular structures, hence involving not only the skin, but also the cellular tissue immediately beneath. The sebaceous glands are most commonly the seat of boils, but occasionally the Meibomian glands (*see*), the ceruminous glands, and the sweat-glands of the armpit, or, more rarely still, the glands of the lips, vulva, or anus are affected.

ÆTIOLOGY.—The *predisposing causes* of boils are—the male sex, middle life; a stout habit of body, seasons of spring and autumn; a diet too full of flesh, or one suddenly changed, such as that adopted during training for rowing, &c. To these must be added the vitiation of the blood during exhausting fevers and in certain cases of saccharine urine, or induced by inhaling dissecting-room effluvia; and dirty occupations, for example, chimney-sweeping or rag-picking. Lastly, boils are sometimes epidemic.

Local causes.—The parts of the skin most exposed to dirt or chafing, the hands and face, the neck and back, the buttocks and knees, are favourite sites for boils; but they may form on any part except the palms and soles. Blisters, poultices, and stimulating liniments occasionally cause them.

To these causes is added by some authors the specific contagion of a parasitic fungoid plant, the mycelium of which by developing in a gland-cell, thereby causes limited necrosis (the slough) of the tissue in which it grows. The truth of this view is not yet clearly established.

SYMPTOMS.—Boils appear either singly, in succession, or several at once, forming then as

eruption on the skin. The solitary boil begins with itching; soon a reddish pimple forms, sometimes tipped with a minute vesicle, in the centre of which a hair may generally be detected. The pimple grows larger and harder, the red area increases and grows darker, and pain begins, stinging at first, then throbbing. In about five days the summit breaks, pus oozes forth, the pain abates, and the hardness diminishes. A day or two later the core, a thread of sphacelated cellular tissue, escapes. The boil then subsides, and healing rapidly takes place; the scar is depressed, and for some time of violet colour. Occasionally the inflammation affects chiefly the cellular tissue beneath the skin; the mass is then softer, more round and clearly circumscribed, and fluctuates like an abscess—this variety forms in the armpit. Rarely, the central slough extends rapidly beneath the surface, and communicates with the surface by several small apertures (*carbuncle*). In other cases the swelling is more diffuse, no core appears at the surface, but a hard very painful pimple is formed, which is long in subsiding (*blind boil*). The furuncular eruption, consisting of groups of small boils, forms successive crops, and thus the disease may continue a long time. Boils are generally limited to a small region, but this is not always the case, and the greater part, even the whole, of the body may be attacked.

The constitutional disturbance is usually mild or slight when the boil is due to local irritation, though it may suffice to render nervous, irritable persons unfit for work. When the boils are caused by exhaustion, the general symptoms are severe and denote great depression. Prostration, agitation, stupor, low delirium, dry brown tongue, sordes, vomiting, and diarrhoea set in, and the case often ends fatally, or recovery is very slow, accompanied by much suppuration. Septic absorption and pyæmia very rarely take place.

Carbuncular Boil of the Face.—There is a rare and often fatal form of boil, the determining cause of which is unknown. It is met with only on the head and neck, notably on the lip. Mild and trifling at first, like an ordinary boil, it rapidly extends by inflammation of the veins or lymphatics, and causes poisoning of the blood. The earliest sign of this fatal change is the occurrence of violent and repeated shivers. The boil becomes a boggy swelling of blackish violet colour; the surrounding tissues become hard and brawny; suppuration ceases; sloughing occurs; the complexion grows earthy, the features, if the boil is on the face, become everted; the skin round the eyes in some cases is puffed out, and the eyes themselves project from the sockets; anxiety and laboured gasping breathing set in; and a violent constricting pain in the head, chest, or belly is frequently experienced. Delirium and coma usually supervene, but sometimes consciousness and terrible suffering remain to the last. The duration from the first shiver to the end is about four days. The veins of the face first inflame, and the phlebitis extends by the veins of the orbit to the sinuses in the skull, to the diploe, &c.; hence abscesses form in the eyelid, the forehead, the meninges, or the brain, and occasionally in distant viscera.

Diagnosis.—A boil is distinguished by the

central cavity and slough—characters peculiar to it. The boil of the face accompanied with phlebitis has been confounded in this country with the 'malignant pustule' of Continental surgeons. The former is still a *boil* with a central core. The '*pustule maligne*' is said to have invariably a large vessel surmounting a brownish eschar, with a ring of smaller vessels round the larger one,—a condition never met with in boils.

Prognosis.—When due to local causes, the prognosis is always good, unless the patient be exhausted by old age or fever, under such circumstances the extensive sloughing and suppuration often lead to a fatal issue.

Treatment.—*General.*—First remove predisposing causes, and invigorate the patient by change of air, outdoor exercise, vapour and Turkish baths. The diet should be moderate and mixed. Alcohol, unless the patient is greatly debilitated, should be given in very moderate quantity, and the form of fermented liquor most habitual to the patient is best, much alcohol taken before the core has loosened increases the pain and throbbing. Occasionally a saline purge should be given. Of empirical remedies, yeast (a tablespoonful three daily) is said to put an end to the repetition of boils. Quinine and perchloride of iron are also used. Quinine should be given to an adult in five-grain doses every six hours, till singing in the ears and headache begin, it should then be gradually lowered for three or four days to three or four grains per diem, and then left off. In obstinate cases the waters of Vichy, Barèges, or Harrogate are believed to remove the disposition to boils. In diabetes omission of sugar-forming food, and the free administration of alkalis are the most effectual remedies. For the exhausting boil of the face, large doses of brandy, with quinine, are required.

Local.—When signalled by itching, a boil may be stopped by plucking out the hair of the inflamed follicle, and in a long succession many boils may thus be prevented. When the areola has formed, if the pain be slight a drop of caustic solution applied to the centre will sometimes check the progress of the boil. A better plan at this stage is to cover the boil with a gullannum and opium plaster (Erasmus Wilson's) spread on leather. Under this treatment pain at once ceases, the inflammation gradually subsides, and the separation of the core proceeds painlessly; when the boil discharges, a hole should be cut in the centre of the plaster, for the escape of the products. When the pain is stinging, and the areola wide, with restlessness and headache, warm poultices are most soothing—those of starch cause pustulation less than linseed meal poultices. Mixing lard with linseed poultice, or sprinkling it with the dilute solution of acetate of lead, has a similar effect. Poultices hasten the expulsion of the slough, but should be discontinued as soon as the hardness changes to doughiness. If the slough is large, the surface may be dressed with lint spread with Peruvian balsam, and the boil carefully protected by means of pads and compresses.

Incisions are now much less employed than formerly. They increase rather than lessen the loss of tissue in ordinary boils, and do not

shorten the duration of the inflammation. They give relief to pain, however, and check the spread of diffused boils. When made, incisions should be free, crucial, or even star-like, and carried beyond the boil. In the rapidly extending boil of the face local treatment is of little avail; the free use of the actual cautery may be beneficial if employed at an early period.

BRUXELLES HILL.

BONE, Diseases of.—Under this head are included:—*Acute and Chronic Inflammation of bone and its membranes, with the consequences thereof, such as Caries, Necrosis, and Abscess, New Growths which arise both within and upon the bone; Malformations; and certain Disorders of Nutrition, namely, Hypertrophy and Atrophy.* Bone-tissue should be regarded as being similar to other connective tissues, but some diseases affecting it are rendered obscure, while others are materially modified, by reason of its meshes being filled with lime-salts.

1. **Inflammation.**—As a matter of clinical convenience, it is usual to consider separately inflammations of the periosteum, of the bone proper, and of the medulla, but it should not be forgotten that these structures are throughout continuous and interdependent, and that disease is rarely exclusively confined to any one of them—it may originate or be chiefly developed in one, but it cannot long exist without involving the others to a greater or less degree.

A. **Periostitis**—*Inflammation of the investing membrane of bone (die Knochenhaut).* By periosteum is usually meant the thin fibrous envelope of the bone in which the vessels for the supply of blood subdivide. But between it and the bone is a layer of osteogenetic cells like the cambium-layer of a growing plant, and immediately external is a layer of cellular tissue, continuous with that of the adjacent parts, these are integral portions of the periosteum, and take an active share in all its diseased processes. Periostitis may be either *acute or chronic.*

(a) *Acute periostitis, osteoperiostitis, acute pyramidal abscess, or acute necrosis.*—This is a formidable, but fortunately comparatively rare, disease, at least in the adult. It attacks the long bones almost exclusively, usually those of delicate children or young adults, in whom active bone-growth is still going on, and the periosteum is highly vascular. Acute periostitis probably never occurs without coincident inflammation of bone, and it is by far the most common cause of necrosis. It will be best to regard it as an acute osteitis and periostitis combined, and to call it *osteoperiostitis*, just as we call inflammation of the bone and of the endosteum *osteomyelitis*. The extent to which the bone and the periosteum are in the first instance respectively involved is always difficult, and sometimes impossible, to determine—it may be inferred from the extent of the necrosis. There are two ways in which the disease may begin—either in the fibrous investing sheath of the bone and the cellular layers beneath and superficial to it, from whence it spreads inwards to the cortical bone-substance, or even to the medulla; or in the bone-tissue—the inflammation spreading outwards to the periosteum. It is impossible

in the living subject to distinguish acute osteomyelitis and osteoperiostitis arising from idiopathic causes. The disease is usually attributed to an injury, often slight, or to exposure to extremes of cold or heat. Frequently no cause is assignable.

PATHOLOGY.—Rapid exudation takes place in the layers of the periosteum, and in the Haversian spaces and canals of the bone, to such an extent as to obstruct the circulation, and probably to cause by pressure the severe pain complained of at the outset. The exudation beneath the fibrous layer of periosteum is copious, and soon becomes purulent, the periosteum is detached; the vascular supply of the bone is cut off, and necrosis results. The extent of the necrosis depends upon the extent to which the periosteum is engaged, while the thickness of the dead bone depends mainly on the depth to which the inflammation in the osseous tissue extends. Large accumulations of pus are often rapidly formed in these cases, the pus escaping through openings in the fibrous envelope into the circumjacent cellular tissue. The shafts of the tibia and femur are the parts most frequently affected, the disease occurs more rarely in the bones of the upper extremities and other parts of the skeleton.

SYMPTOMS.—One of the earliest symptoms of acute periostitis is sudden and severe pain in the affected bone, which is soon followed by intense fever. On the second or third day deep-seated swelling sets in, somewhat obscure at first. After an interval varying from five to ten days, the inflammatory signs approach the surface, the skin becomes oedematous, pits on pressure, and finally reddens and inflames. The length of interval depends on the thickness of muscles and soft parts covering the affected bone. Other things being alike in respect of pain and amount of fever, the longer the delay in the appearance of external swelling, the greater the probability that the bone is the first and chief tissue engaged, the inflammation having reached the periosteum secondarily, while the early appearance of swelling and fluctuation externally suggest that the inflammation is chiefly periosteal. Blood-poisoning, either septicæmic or pyæmic, is a common consequence of acute inflammation of bone and periosteum.

DIAGNOSIS.—This disease may be obscure at the commencement, and its nature overlooked; it has often been mistaken for acute rheumatism on account of the swollen joints, for phlegmonous erysipelas, for acute cellulitis, or for typhoid fever. The only malady with which acute periostitis need be confounded is an idiopathic inflammation of the deep-seated cellular tissue in a limb. This disease is rare. When we observe the chain of symptoms above described in a young person, we may safely assume the presence of an acute osteoperiostitis. The disease almost invariably terminates in suppuration and necrosis; resolution happens rarely, but necrosis is not inevitable, even after suppuration. In a few cases, especially in young children, if the matter be speedily evacuated, the abscess collapses, the periosteum reunites with the bone, and no necrosis takes place. This result is unfortunately quite exceptional.

PROGNOSIS.—This must be founded on the

extent of the necrosis; whether blood-poisoning has taken place; and whether the adjacent joints are implicated in the disease. Cure cannot take place until the dead bone is cast off or removed, and this is often long delayed. The usefulness of a limb may be permanently impaired by the disease, or it may require amputation, or the patient may lose his life altogether. On the other hand, the use of the limb, and the health of the patient, may become completely re-established.

TREATMENT.—Early and energetic treatment is of the greatest importance, as it affords the best prospect of averting the disastrous consequences of acute periostitis, but in hospital practice the cases are rarely seen sufficiently early. In the first stage the limb should be elevated, and ice applied; painting the limb with a strong solution of iodine is advisable. As soon as the nature of the affection is manifest, incisions down to the bone, so as to divide the periosteum, are indicated even before pus is formed. They relieve pain and tension, and, by permitting the timely escape of pus as soon as it does form, the amount of periosteal separation, and consequently of necrosis, is limited. It is the more important to make an early incision, because evidence of fluctuation is at first by no means clear or easy to make out, and this should, therefore, be done in all cases of doubt. Antiseptic precautions should always be taken. Sometimes the abscess cavity does not readily collapse, owing to its walls being stiff and infiltrated, and its contents may become purid, thus greatly increasing the patient's risks. If there be synovial effusion into a neighbouring joint, the limb should be kept at rest by means of a splint or a fixed bandage. When the acute symptoms subside, the abscess-cavity contracts, one or more sinuses remain, and the dead bone begins to separate (see *Necrosis*).

Where the epiphysis is engaged in the disease the case is more urgent, the fever runs higher, the suppuration is greater, and the degree of joint-implication more intense, proceeding in extreme cases to suppurative inflammation and destruction of the articulation. The oedema of the limb often indicates a deep-seated phlebitis, the precursor of septic poisoning. Under these circumstances, amputation of the limb is often the only resource. It is imperative to amputate where there is extensive bone-destruction, and the symptoms indicate commencing pyæmia, or where, with the death of a large portion of the shaft, one or both of the neighbouring joints has become gravely implicated, and great suffering and loss of strength forbid us to temporise. It is precisely in these cases, however, where the diaphysis has become increased up to the epiphyseal junction, that good results are attainable by the immediate extraction of the dead bone. The shaft where it joins the epiphysis becomes rapidly detached and loose, and may easily be separated, while the bone can be divided with a chain saw beyond the limit of the necrosis in the other direction, and removed. It is difficult, however, in the early stages to diagnose the extent of the necrosis. Where the joints both above and below are involved, amputation is usually necessary.

A periostitis of a very acute form, almost

invariably suppurating, and accompanied by necrosis, is very common in the fingers, where it chiefly affects the ungual phalanges. The pain is very great, but may be relieved by an early and free incision down to the bone, which, nevertheless, does not usually avert either suppurating or necrosis.

(b) *Chronic periostitis* is usually due to some diathetic cause, but may result from injury, or from some continuous pressure. It is most frequent on the superficial parts of the skeleton, as the tibia, clavicle, skull, and ribs, but may affect any bone; and it is often observed at the origin or insertion of muscles. When the disease arises from a general cause, such as syphilis, many parts of the skeleton are affected; when from a local cause, usually only one.

SYMPTOMS.—Chronic periostitis generally takes the form of what is called a *nodule*—a tender, more or less painful, rounded or oval swelling, at first tense and hard, afterwards soft or, or even fluctuating. The pain is much greater at the outset, from the tension of the parts involved, and is generally worse at night. Subsequently the swelling becomes indolent, and painless, unless pressed upon. Nodules are due to a localised inflammation. The cambium-layer of the periosteum and its external layer proliferate and become filled with leucocytes, thus forming a well-marked projection on the bone, which may undergo resolution, suppurate, or ossify, according to circumstances.

PROGNOSIS.—In chronic periostitis this is usually favourable. Under the influence of early and suitable treatment, the inflammatory products are completely absorbed, and the bone resumes its natural shape. If the chronic inflammation of the periosteum be permitted to proceed unchecked, a deposit of new osseous lamellæ usually takes place on the surface of the affected bone, giving rise to permanent thickenings, or even to osteophytic growths. These are composed of light porous bone, with a rough surface. The skeleton of a syphilitic subject will often present numerous thickenings of this nature. On making a section of the bone, it is easy to see that the new bone is superimposed upon the old, and is formed by the periosteum.

TREATMENT.—When due to a local cause, the swelling will often spontaneously subside with rest to the part, but in obstinate cases iodide of potassium internally, and iodine ointment or blistering externally, may be required. If the subject be unhealthy, or if the original injury be considerable, suppuration may take place, when the treatment will be that of an *inflammatory abscess*. *Syphilitic nodules*, which are a very common expression of chronic periostitis, yield rapidly to the influence of iodide of potassium, which in some cases may usefully be combined with a mercurial course. Blistering or friction externally is harmful in such cases. Syphilitic nodules are not at first prone to suppurate, and even when they become soft and fluctuating, and the skin reddens over them, they should not be mistaken for abscesses, as they readily become absorbed under suitable treatment.

(c) *Periostitis after typhoid fever*.—A peculiar form of chronic periostitis is occasionally observed as a sequel to typhoid fever. It occurs during

shorten the duration of the inflammation. They give relief to pain, however, and check the spread of diffused boils. When made, incisions should be free, crucial, or even star-like, and carried beyond the boil. In the rapidly extending boil of the face local treatment is of little avail; the free use of the actual cautery may be beneficial if employed at an early period.

BRECKLEY HILL.

If there be synovial effusion into a neighbouring joint, the limb should be kept at rest by means of a splint or a fixed bandage. When the acute symptoms subside, the abscess-cavity contracts, one or more sinuses remain, and the dead bone begins to separate (*see Necrosis*).

Where the epiphysis is engaged in the disease the case is more urgent; the fever runs higher, the suppuration is greater, and the degree of joint-implication more intense, proceeding in extreme cases to suppurative inflammation and destruction of the articulation. The oedema of the limb often indicates a deep-seated phlebitis, the precursor of septic poisoning. Under these circumstances, amputation of the limb is often the only resource. It is imperative to amputate where there is extensive bone-destruction, and the symptoms indicate commencing pyæmia; or where, with the death of a large portion of the shaft, one or both of the neighbouring joints has become gravely implicated, and great suffering and loss of strength forbid us to temporise. It is precisely in these cases, however, where the diaphysis has become necrosed up to the epiphyseal junction, that good results are attainable by the immediate extraction of the dead bone. The shaft where it joins the epiphysis becomes rapidly detached and loose, and may easily be separated, while the bone can be divided with a chain saw beyond the limit of the necrosis in the other direction, and removed. It is difficult, however, in the early stages to diagnose the extent of the necrosis. Where the joints both above and below are involved, amputation is usually necessary.

A periostitis of a very acute form, almost

invariably suppurating, and accompanied by necrosis, is very common in the fingers, where it chiefly affects the ungual phalanx. The pain is very great, but may be relieved by an early and free incision down to the bone, which, nevertheless, does not usually avert either suppuration or necrosis.

(b) *Chronic periostitis* is usually due to some diathetic cause, but may result from injury, or from some continuous pressure. It is most frequent on the superficial parts of the skeleton, as the tibia, clavicle, skull, and ribs, but may affect any bone; and it is often observed at the origin or insertion of muscles. When the disease arises from a general cause, such as syphilis, many parts of the skeleton are affected; when from a local cause, usually only one.

SYMPTOMS.—Chronic periostitis generally takes the form of what is called a *nodule*—a tender, more or less painful, rounded or oval swelling; at first tense and hard, afterwards softer, or even fluctuating. The pain is much greater at the outset, from the tension of the parts involved, and is generally worse at night. Subsequently the swelling becomes indolent, and painless, unless pressed upon. Nodes are due to a localised inflammation. The cambium-layer of the periosteum and its external layer proliferate and become filled with leucocytes, thus forming a well-marked projection on the bone, which may undergo resolution, suppurate, or ossify, according to circumstances.

PROGNOSIS.—In chronic periostitis this is usually favourable. Under the influence of early and suitable treatment, the inflammatory products are completely absorbed, and the bone resumes its natural shape. If the chronic inflammation of the periosteum be permitted to proceed unchecked, a deposit of new osseous lamellæ usually takes place on the surface of the affected bone, giving rise to permanent thickenings, or even to osteophytic growths. These are composed of light porous bone, with a rough surface. The skeleton of a syphilitic subject will often present numerous thickenings of this nature. On making a section of the bone, it is easy to see that the new bone is superimposed upon the old, and is formed by the periosteum.

TREATMENT.—When due to a local cause, the swelling will often spontaneously subside with rest to the part, but in obstinate cases iodide of potassium internally, and iodine ointment or blistering externally, may be required. If the subject be unhealthy, or if the original injury be considerable, suppuration may take place, when the treatment will be that of an *inflammatory abscess*. *Syphilitic nodes*, which are a very common expression of chronic periostitis, yield rapidly to the influence of iodide of potassium, which in some cases may usefully be combined with a mercurial course. Blistering or friction externally is hurtful in such cases. Syphilitic nodes are not at first prone to suppuration, and even when they become soft and fluctuating, and the skin reddens over them, they should not be mistaken for abscesses, as they readily become absorbed under suitable treatment.

(c) *Periostitis after typhoid fever.*—A peculiar form of chronic periostitis is occasionally observed as a sequel to typhoid fever. It occurs during

convalescence, and without general symptoms. It takes the form of hot, painful, and tender nodes, frequently symmetrical, and often placed on the tibia; the disease is also found on the ribs and other bones. It may be associated with necrosis, but if so the extent of the dead bone is small in proportion to the inflamed area of periosteum. The general health is not seriously affected, and the disease is very amenable to treatment by iodide of potassium, combined with iodide of iron.

B. *Osteitis* is an inflammation chiefly affecting the bone-substance; this form may also be *acute* or *chronic*.

(a) *Acute osteitis* is neither clinically nor pathologically to be distinguished from acute osteomyelitis or endosteitis (see *Osteomyelitis* s).

(b) *Chronic osteitis* is a disease beginning in the bone, in which the chief changes from first to last occur, the periosteum being secondarily engaged. This affection may result from injury, or be excited by exposure to cold; but it often depends on constitutional predisposition, such as the syphilitic, the strumous, the gouty, or the rheumatic diathesis, the first being the most frequent cause. It may occur in any part of the skeleton; the chief changes, when produced by syphilis, occur in the shafts of the long bones. They consist mainly of hypertrophy, and the bone is ultimately increased in thickness, in length, and generally in density: its interior is often transformed into dense bone-tissue, and the medullary cavity is obliterated. Another form, associated with the strumous diathesis, is generally seated in the joint-ends of the long bones and in the spongy bones. It is prone to end in suppuration, accompanied by either caries or necrosis. The gouty and rheumatic forms are associated with evidence of the presence of either of these diatheses.

PATHOLOGY.—Increased vascularity first takes place, the Haversian canals enlarge, the canaliculi disappear, the cancelli enlarge to contain the inflammation-products, and the earthy matter diminishes; hence the inflamed bone softens, and, if macerated at this stage, will be found comparatively light and porous. When the inflammation affects the superficial laminae of the bone, the periosteum becomes thick and vascular; if the deeper parts are involved, similar changes will occur in the endosteum. The porous condition of the bone may become permanent, when the condition is called *osteoporosis*, the result of so-called rarefying *ostitis*; or the granulations become transformed into new bone, and the cancellated structure is filled with osseous deposit, so that the whole of the inflamed area becomes very dense, and is then said to be sclerosed; or the inflammation-process may terminate in suppuration, followed by caries, necrosis, or an abscess of the bone, which last may be either diffused or circumscribed.

SYMPTOMS.—These are insidious, very obscure at the outset, and may be mistaken for those of chronic rheumatism, or mere periostitis. They consist chiefly in aching, gnawing pain in the affected bone, with characteristic remissions and nocturnal exacerbations. The bone is tender on pressure, and feels increased in bulk at first, from the infiltration of the immediately sur-

rounding soft tissues; subsequently the bone itself enlarges. There is often increase of heat in the limb. The progress is very chronic, and if unchecked by treatment may give rise to considerable deformity.

TREATMENT.—This should be directed to the cause of the disease. If this be syphilis, an antisyphilitic treatment will be followed by good results; even in chronic bone-inflammation, not dependent on syphilis, iodide of potassium is often of great service. Local counter-irritation may also be employed. Often the cause cannot be made out, and if iodide of potassium fail in producing an effect, we must fall back on general treatment. In the early subacute stage, rest, with elevation of the affected part, is very desirable. Warm fomentations, followed by iced compresses, relieve the suffering. If there be much pain and tension, leeches should be applied. Puncturing the tissues down to the inflamed bone with a tenotomy knife or fine bistoury, relieves the tense periosteum, and allows extravasation beneath it to escape, so that the pain is promptly abated.

(c) *Osteitis deformans*.—A peculiar form of chronic inflammation of bone has been described by Sir James Paget under this title, from the changes it produces, both in the form and density of the affected bones. It is a chronic osteitis of the most extreme type. It begins in middle age, and may continue for an indefinite time without influence upon the general health, which distinguishes it clinically from other bone-inflammations. It is usually symmetrical, and affects chiefly the long bones of the lower extremity and the skull. At first the bones enlarge and soften, from excessive production of imperfectly developed structure and increased blood-supply, and, yielding to the weight of the body, become curved and misshapen, but the limbs, although deformed, remain strong and fitted to support the body. In its early period, and sometimes throughout its course, the disease is attended with pains in the affected bones, which vary widely in severity, and are not especially nocturnal or periodic. It is not attended by fever, nor associated with any constitutional disease. It differs from the chronic osteitis dependent on simple inflammation of bone or that produced by gut or syphilis, in affecting the whole length of the bone. Hyperostosis and osteoporosis dependent on these latter causes rarely affect the entire bone. No treatment appears to produce any effect upon this disease.

C. *Osteomyelitis* is an inflammation chiefly affecting the interior structure of the bone. Like the former, it may be *acute* or *chronic*.

(a) *Acute osteomyelitis* or *endosteitis* is a suppurative inflammation of the medulla and bone, which very frequently ends in septic poisoning and necrosis. It is nearly always associated with bone-injury, and most frequently happens after amputation, or gunshot fractures, in which the cancellated structure is injured, a severe contusion of the bone, an injury to the periosteum, or exposure to sudden extremes of heat and cold is capable, under some circumstances, of producing the disease.

SYMPTOMS.—The symptoms are obscure, more especially if there be no opportunity of examining

the affected bone, as the changes in the bone are often masked by inflammation of the superficial parts. They usually make their appearance from five to ten days after the injury to the bone. The pain may not be excessive; there is fever and perhaps rigor. If there be a wound the secretion from it diminishes in quantity, and becomes less healthy; the medulla protrudes from its central cavity; the part soon becomes surrounded by putrescent fluid; and the symptoms become those of more or less intense septicæmia. The periosteum sometimes, but not always, separates from the bone. In young persons the disease is sometimes arrested at the epiphysis; but in the adult the whole length of the bone is liable to be affected. The risk of septic poisoning is infinitely greater in osteomyelitis than in osteo-periostitis. Thrombosis of the bone-veins is especially prone to happen, and by the breaking down of the clot septic emboli are carried into the circulation, and deposited in the liver, lungs, and elsewhere. It is in this disease, too, that fatty embolism takes place—a condition associated with a very acute and fatal form of blood-poisoning. The prognosis is generally bad. It is impossible to distinguish acute osteomyelitis from acute osteo-periostitis, arising from non-traumatic causes. In military hospitals, in war time, acute osteomyelitis is often epidemic.

TREATMENT.—Where the symptoms lead us to suspect osteomyelitis, although the medullary cavity of the bone may not have been exposed, it may be desirable to trephine the bone, and if suppuration in its interior be discovered, it will be necessary to amputate, and as soon as the nature of the disease is recognised, this affords the best chance of saving the patient's life. The chief difficulty consists in arriving at a correct diagnosis and deciding when it becomes necessary to interfere. This may best be done by observing the general progress of the case, and locally by the introduction of a probe into the medullary cavity when this is exposed. If it reach healthy bleeding medulla near the surface, we may temporise, if the constitutional symptoms admit of this; but it is rare for the disease once commenced to be limited—it has an extreme tendency to become diffused. Experience shows that nothing short of amputation at, or even above, the next joint is sufficient to arrest the consequences of the malady, and this must be done before the systemic poisoning has become marked. Amputation in the continuity of the affected bone is worse than useless.

(b) *Chronic osteomyelitis* is an obscure affection, not to be distinguished, either clinically or pathologically, from chronic osteitis. It may terminate in sclerosis, or in the formation of an abscess. See Chronic Osteitis.

2. **Abscess.**—This is a term applied usually to a limited supuration in the bone, unattended by necrosis. Young adults are most prone to the disease, or boys about the age of puberty; it is very rare in women. It is the result of a chronic inflammation of bone, which may be associated with some injury. This affection is most frequently met with in the upper or lower extremities of the tibia, just external to the epiphyseal cartilage, less frequently in the ends of

the femur, only occasionally in other bones, and very seldom in the compact tissue anywhere.

SYMPTOMS.—A circumscribed, slightly elevated, very tender and painful swelling may be discovered. This is due to a local periostitis with new bone-deposit, and the bone itself is often half an inch or an inch longer than its fellow, by reason of increased activity of growth at the epiphysis. The skin and superficial parts are unchanged at first, or there may be but trifling subcutaneous œdema. There is often slight local increase of temperature. The pain, on deep pressure at the central point, is often intolerable. It is intermittent at first, but generally worse at night. After a time it becomes continuous, and deprives the patient of all rest, owing to its severity. The abscess may persist with little change for months or years. The symptoms generally resemble those of osteitis, from which at the outset it is difficult to distinguish this affection. When the abscess tends to reach the periosteal surface, the soft parts become engorged, and there will be slight redness and œdema of the skin. Rarely the pus makes its way into the adjacent articulation, in which it sets up destructive inflammation; but usually the joints are free from implication. The subjects of the disorder have often suffered from antecedent bone-disease. Evidence of this should be looked for, as giving a clue to the diagnosis.

TREATMENT.—Spontaneous cure cannot occur—even if the abscess discharge itself, a permanent fistula will usually remain. It is necessary freely to lay open the abscess-cavity. A crucial incision must be made through the soft parts, down to the bone, at the most tender and prominent point, and a disc of bone removed by the bone-trephine—an instrument without a shoulder, about half-an inch in diameter. The sudden loss of resistance indicates the piercing of the abscess-cavity. The layer of granulation-tissue lining its interior should not be interfered with, but the cavity simply washed out. The pus is often foul, and greenish in colour. The wound should be dressed antiseptically; granulations presently fill it, which are subsequently transformed into a fibrous cicatrix. Immediate and permanent relief follows the operation. If the abscess is missed, the trephine may be re-applied, or drill punctures made in the most likely directions in the adjacent bone, in order to discover the pus. Sometimes an error of diagnosis is committed, and the symptoms are found to arise from chronic osteitis, without suppuration. The operation, however, affords relief in these cases also. Where there is doubt, a preliminary course of iodide of potassium will often resolve it.

3. **Caries** is a form of chronic inflammation of bone, which has been likened to the process of ulceration in the soft tissues. It is generally found in the spongy bones, in any part of the skeleton, the vertebrae and tarsus being the parts most commonly affected. There are two forms of the disease—one, *simple caries*, resembles an indolent ulcer of the soft parts, is most common in the flat or short bones, but is sometimes met with in the compact tissue of long bones; the other, *fungating caries*, is often met with in the articular ends of the long bones, and usually

terminates in joint-disorganisation. It has been called *subarticular caries*; and is part of the disease known as *tumor albus* (see JOINTS, Diseases of). The non-articular form of simple caries often originates in a localised periostitis, and is generally due either to syphilis or struma—the latter is most frequent in young persons, the former in adults.

PATHOLOGY.—In caries the bone gradually disintegrates as the result of a chronic inflammation of its cancellated tissue. The trabeculae become infiltrated with leucocytes, and granulations form, which prove the source of purulent discharge, just as in a granulating surface of the soft parts; but the process is interfered with and delayed by the act of getting rid of the osseous structure, in the trabeculae of which the cells remain shut up until the dead bone finally breaks down, and comes away in the discharges, being often distinguished in the form of gritty particles. Until this process is completed the dead bone is soaked in pus, which often becomes putrid, and until it is got rid of a healthy granulation-surface is impossible.

SYMPTOMS.—Caries is very chronic in its progress, and often causes extensive loss of bone, destruction of a joint, or loss of a limb. It is almost always associated with an impaired condition of general health, the adjacent soft parts are involved in the inflammation; abscesses form in them, generally connected with the diseased bone; these burst or are opened, and sinuses lined with gelatiniform granulations, and discharging a thin pus, persist for an indefinite time. On examination with the probe the surface of the bone is felt bare, rough, and much softened; and outside the area of carious bone periosteal deposits of newly-formed osseous tissue are often found. The diagnosis and prognosis depend upon the age, constitutional condition, and history of the patient, as much as on the local signs.

TREATMENT.—This must be directed to relieve the constitutional taint, as well as the local disease. Merely to excise or destroy the diseased portion of bone is not sufficient to cure the patient. Local means prove efficient only when the general condition has been sufficiently ameliorated, especially in the unhealthy chronic inflammation of bone frequently called strumous. Good air, good food, and tonics are, therefore, of great importance. If syphilis be present, an anti-syphilitic treatment must be pursued. The principle by which the local means act is to facilitate the formation of a healthy granulating surface—to transform, in fact, an indolent into a healing ulcer. The disintegration of the dead and diseased trabeculae must be assisted. For this purpose the application of strong sulphuric acid diluted by two or three parts of water, or some other mineral acid, often proves useful. Partial gouging out of the diseased bone seldom succeeds, because of the injury done by the instrument to the adjacent bone, weakened as it is by inflammatory changes, and therefore prone to set up fresh disease. The complete *evident* of the bone, leaving nothing but its thin outer shell, is more successful; but when the disease begins to invade adjacent joints, as in the tarsus, excision of the entire bone is best; or when several bones are involved, amputation becomes

necessary. In children operations of this kind are not so often required; general treatment usually proves sufficient. In the early stages the actual cautery, applied over the most painful spot, is a valuable counter-irritant. It is undesirable to make early incisions into strumous abscesses in connection with diseased bone. It is better to empty them by a small trocar, and to preserve the diseased area as long as possible from atmospheric influence. When the carious action is arrested, the cavity fills with healthy granulations, the sinuses close, the parts cicatrize, and the gap in the osseous tissue is filled by fibrous, or sometimes by osseous material.

4. **NECROSIS.**—The complete arrest of nutrition in a portion of bone from any cause is followed by the death or necrosis of the bone, and by a series of inflammatory changes in the adjacent parts, which result in the complete separation of the dead from the living tissue.

ETIOLOGY.—Necrosis is most frequently the result of acute bone-inflammation or severe injury, as after amputation, fracture, or contusion. It is especially prone to happen in the compact tissue, but it also occurs in the spongy structure, as the joint-ends of long bones, or the tarsus and carpus, where it is usually associated with more chronic forms of inflammation, and is more limited. The peculiar nature of the blood-supply to bone, and the facility with which it may be interfered with or arrested under the pressure of inflammatory changes, go far to explain the frequency of necrosis as a result of bone-inflammation. Acute suppurative osteoperiostitis or osteomyelitis rarely terminates without necrosis. Whether the dead bone will be in the superficial or the deep lamellae depends on the seat of the inflammation, and on the extent to which the periosteum and endosteum are respectively implicated. The long-continued action of phosphorus, as observed in match-makers, and also of mercury, may induce necrosis. Syphilis is a frequent cause of necrosis, through its tendency to produce chronic osteoperiostitis the sclerosed bone thus originated being afterwards prone to necrose. It is not an uncommon sequel during convalescence from some eruptive and continued fevers. After scarlatina, osteoperiostitis, followed by necrosis, is by no means rare, although affections of the joints are more common. It is probable that many cases of necrosis occurring in childhood are connected with an antecedent attack of scarlet fever. The nasal bones may necrose as the result of severe coryza, the vertebrae after pharyngitis, or the petrous portion of the temporal bone as a consequence of otitis. Arterial thrombosis and embolism are occasional sequelae of typhus, and may produce a local gangrene, not only of the soft parts, but of bone. This is, however, more frequent in connection with typhoid fever. In endocarditis the nutrient artery of a bone has been observed to be obliterated by an embolus, thus producing necrosis.

PATHOLOGY.—After the death of a portion of bone, the living tissue, in immediate contact with the dead, becomes inflamed. The Haversian canals and canaliculi become distended with migratory cells; loops of capillaries form from the pre-existing vessels; a granulating surface, in fact, surrounds the dead bone in a manner precisely

similar to what takes place in the soft parts when a slough is being thrown off. The periosteum separates from the bone, becomes thick and vascular, while the osseous surface beneath is smooth and white, like macerated bone. In cases of syphilitic necrosis, as well as in that resulting from phosphorus, the surface is rough from antecedent peritoneal deposit. How the osseous trabeculae are dissolved or disintegrated over the surface of separation, so as to loosen the dead bone, is not certain. Probably the granulation-tissue that forms from the living bone possesses amoeboid properties, and thus disposes of some of the bone-particles. The pus that is formed has a mechanical influence, while according to one theory lactic acid is produced, which transforms the insoluble into soluble salts of lime. While this loosening process is going on new bone, formed chiefly from the periosteum, is being deposited, constantly becoming thicker, and with one or more openings in it for the escape of pus, called *cloaca*, so that eventually the dead piece becomes completely invaginated, and is named, from its position, a *sequestrum*. This sequestration of the dead bone is not invariable, as for instance in the spongy bones, the bones of the skull, and the upper jaw, or where from any cause the periosteum has been destroyed, no sheath of new bone will be formed. Necrosis very rarely takes place without suppuration, when this does happen the nature of the case is very obscure. Occasionally nearly the whole shaft of a long bone has been found necrosed, and after an interval of months or even years no suppuration may have taken place. Such forms of necrosis closely simulate malignant disease, and often they cannot be relieved or even recognised save after amputation. A chronic osteitis, followed by hypertrophy and sclerosis of the bone, is the most common antecedent condition of this form of necrosis.

TREATMENT.—The changes already described, which separate the dead bone from the living, do not cause its expulsion from the body. On the contrary, they shut it up, like a kernel within its shell, and nothing so imperatively demands surgical interference as the presence of necrosed bone. It acts as a foreign body, is a constant source of risk to the patient, and should be removed as soon as practicable. Its presence excites the periosteum to further formation of bone, so that the invaginating sheath becomes of great thickness in old-standing cases. The period at which an operation is usually undertaken is when the sequestrum has become loose, and the time required for this purpose varies with the extent and thickness of the necrosed bone. In the actively growing bones of the young the process of separation is accomplished more quickly than in the adult, especially when the sequestrum involves the epiphyseal junction. Roughly estimated, a period of from three to six months might be named as that within which loosening of the sequestrum usually occurs. Beyond the latter term an effort to extract the dead bone should not be delayed, even if it cannot be felt to be loose. Among other risks involved in doing so may be that of amyloid degeneration of the viscera, principally the liver, kidneys, and spleen, which are subject to this change as the conse-

quence of long-continued discharge from bone-disease. In order to remove a sequestrum, a director should first be introduced through a cloaca as a guide, and the soft parts sufficiently divided. An adequately large opening must now be made in the encasing sheath of new bone with the chisel, trephine, small saw, or cutting forceps, and the dead bone extracted, either in one or several pieces, as may be the more convenient. The operation may prove difficult on account of great thickness of the soft parts or of the sequestrum envelope, or because the sequestrum itself is extensive. After the removal of the dead bone the cavity fills with granulations, which subsequently ossify, and the soft parts cicatrize. Finally the sequestrum envelope of new bone is partly absorbed, partly consolidated, just as the redundant callus is after fracture, and the bone tends more or less to resume its normal size and shape.

5 Tubercle.—An examination of some cases of chronic bone-disease in scrofulous subjects seems to prove their connection with the formation of tubercle in the bone. The medullary tissue in the joint-ends of the long bones, and cancellated bone generally, are chiefly affected. The external appearances are those of fungating caries; but microscopic examination discloses multitudes of round cells like lymph-corpuscles, with protoplasmic matter, filling up the interspaces. The cells are found surrounding the soft, gray, non-vascular patches, which are often seen on section of an inflamed cancellated bone in scrofulous individuals, the central part of which may be the subject of calcareous, fatty, or suppurative changes. The bone when so affected is never sclerosed; hence these are not simply cases of chronic inflammation. There is, however, some difference of opinion as to whether, in strictness, they should be called tubercular in their nature, and the inference that they are so rests rather on the general condition of the patient than on any purely local characteristic.

TREATMENT.—In cases of this kind general tonic treatment becomes of the greatest importance. Rest must be given to the affected part, and exercise to the body generally, combined with fresh air both day and night, and simple nourishing food. Where the bone is extensively diseased, it must either be excised, or the part amputated. The presence of the tubercular diathesis does not forbid an operation, the local source of irritation and drain upon the system being thus removed, and a healthy traumatic surface substituted for one infiltrated with inflammation-products. The removal of the local disorder often proves a comfort to the patient, and increases his chance of regaining health and strength.

6. New Growths.—The bones are liable to most of the new growths forming tumours found elsewhere in the body, such as cancerous, vascular, and other tumours. The most important are the following:—

a. Some tumours are peculiar to bone, as, for instance, the *Myeloid*, so called from the many nucleated corpuscles contained in it, analogous to those found in fetal marrow; it is of endosteal origin, causing an expansion of the bone in which it grows. It is most common in the maxillary bones, and near the epiphyseal ends of the long bones. It is generally observed in

young persons, requires removal, and extirpation, if complete, is not, as a rule, followed by a return of the disease.

b. Periosteal or Fasciculated Sarcoma. springing from the periosteum of a long bone, such as the femur, is not uncommon. The shaft of the bone may be seen on section passing through the centre of the tumour. Numerous bands of fibrous tissue, often ossified, radiate from the periosteum through the growth, like an out-spread fan. The best treatment is amputation of the limb at the joint above, which does not, however, ensure against recurrence of the disease.

c. Enchondroma.—This is a bony outgrowth developed on any part of the skeleton. It is difficult to distinguish cartilaginous from osseous outgrowths. The two structures are often mixed, and a tumour originally cartilaginous is often transformed into bone. Cartilaginous outgrowths, called *enchondromas* are met with on the costal cartilages of old persons, also on the intervertebral discs, near the synchondroses, and arise also from the articular cartilages in rheumatic arthritis. Cartilaginous tumours, growing either from the periosteum or the medulla, have their favourite seat upon the phalanges; they are usually multiple, and from the deformity and inconvenience they produce often demand either enucleation of the tumour or, in extreme cases, amputation of the finger. The more special forms of exostosis are of two kinds, the *spongy* and the *ivory-like*. *Spongy exostosis* is often developed near the articular ends of the long bones, where it forms a nodulated outgrowth of cancellated bone of variable size, encrusted with a thin layer of cartilage, and having generally a bursa superimposed. This kind of exostosis is often connected with the epiphyseal cartilage, and ceases to grow when the bone is fully developed. This fact, as well as the proximity of the neighbouring joint, renders surgical interference generally unnecessary, and often hazardous. Another form of spongy exostosis, sometimes called *osteophyte*, depends on a local excessive periosteal growth of bone. At first this outgrowth is porous, and but slightly connected with the bone on which it is developed. Afterwards it may become dense and hard from interstitial deposit, or it may always remain spongy. Such exostoses often depend on some local exciting cause, such as a blow; or they may be found at the insertion or origin of a muscle, as in the so-called rider's bone, at the origin of the adductor longus muscle, or the exostosis frequently found at the insertion of the adductor magnus, or the 'exercise bone' of the German soldier. They may be regarded as morbid exaggerations of the normal tubercities of the skeleton. *Ivory exostosis*, so called from its dense, aburnated character, is more rare. It varies much in size, and may be pedunculated or sessile. Hereditary influence appears to exist in some cases, in others a predisposition to chronic periostitis, but there may be no apparent cause. The development is slow and painless.

Treatment.—Interference is seldom required in the spongy exostoses, except on account of pain or loss of function. When pedunculated they can be broken off or divided subcutaneously; and although they may reunite, it will probably

be in a more convenient and painless relation to adjacent parts. Otherwise they should be excised.

Except on account of deformity, or of pressing on important structures, an ivory exostosis need not be meddled with. It can often, however, when necessary, be enucleated; and where only a partial removal is possible, the low vitality of the tumour often causes necrosis and subsequent exfoliation of the remainder. Spontaneous necrosis also occasionally occurs.

d. Osteo-aneurism.—Certain sarcomata and myeloid tumours, when very vascular, pulsate, and have been mistaken for aneurism. There are, however, undoubted cases of aneurismal tumours dilating the bone, which have been cured by ligature of the main vessel of the limb. When the tumour is small it may be excised, or the actual cautery applied. Sometimes amputation is required. The causes and pathology of the disease are obscure. It is probably in some cases of a naevoid character.

e. Bone-cysts are tumours distending and thinning the bone, and filled with serum or bloody fluid. In some rare cases they contain hydatids. The origin of bone-cysts is obscure, some originate in the dentigerous cavities of the maxilla, in which bone-cysts are most frequent, but they are sometimes found elsewhere. A very slow, painless increase in size takes place. The bone becomes gradually very thin, and often affords on pressure a peculiar and characteristic parchment-like crackling. In obscure cases an exploratory puncture should be made.

Treatment consists in freely laying open the cyst-cavity, and providing for subsequent drainage. The cavity gradually contracts and becomes obliterated.

f. Hydatids.—The formation of echinococcus-cysts in bone is exceedingly rare, compared with other parts of the body. The causes are unknown, and the symptoms very obscure, resembling those of an ordinary cyst. A cavity is formed, usually in the spongy extremities of the long bones, to contain the mother cyst. But it is also found in the medullary canal. The affection is grave. Serious inflammation often follows interference with these entozoa. It is sometimes difficult to remove the whole disease; and unless this be effectually done a relapse will occur; while in such parts as the pelvis art is unavailing. The cavity should, if possible, be freely laid open, and all the cysts carefully removed or destroyed. The actual cautery may be sometimes employed with advantage, or the surface of the adjacent bone removed, as it may be invaded by the cysts. An exploratory puncture can alone resolve the diagnosis, by finding the hooks of the accephalocyst in the fluid.

7. Malformations.—These consist in any departure from the normal type of the skeleton, by reason of excess, deficiency, or irregularity, either congenital or acquired. It is not necessary more than to allude to the fact, that the skeleton is often defective in parts; that senile changes occur, especially in certain bones; and that supplementary bones and processes are met with. Various deformities occur in bones from fractures, both intra-uterine and subsequent to birth, and from curvatures due to rickets or

swelling. Treatment of curvature consists in gradual straightening by splints or other apparatus, or immediate straightening under chloroform, methods which, in the soft growing bones of the young, prove successful in abating many deformities. The curvatures of adult bones do not yield in this way. When there is loss or impairment of function from deformity, the bone may be safely divided subcutaneously with the chisel or saw, and the limb straightened—often with admirable results. Foreible fracture is a clumsy and somewhat dangerous method, as the force employed cannot be regulated.

8. **Hypertrophy** means an excessive growth of bone-tissue. Apart from inflammation this is rare, but in museums specimens of excessive growth are met with, especially of the bones of the face and skull. The causes are unknown, and no treatment appears applicable.

9. **Atrophy** consists in a diminution of the size or compactness of a bone. It may be the result of inflammatory changes, of senile degeneration, of disuse of a limb, or of an injury, such as a fracture followed by non-union. The bone-tissue gradually wastes away, the cortical portion often becoming a thin parchment-like layer of bone, filled with soft medulla. This has been called *eccentric atrophy*. The external appearance and size of the bone remain unchanged. *Concentric atrophy*, where the size of the bone diminishes in all its dimensions, may occur in bones which have been disused for lengthened periods, as from paralysis of a limb, disuse of a joint, or un-united fractures. *Spontaneous fractures*, or fractures due to trifling causes, are very common under these circumstances. The term *Fragilitas Ossium* has been applied to this condition of bone-tissue, which also frequently occurs in cases of cancerous cachexia.

10. **Softening**.—This change occurs in Rickets and Mollities Ossium. See RICKETS, and MOLLITIES OSSIIUM. WILLIAM MACCORMAC.

BOBORYGMI (*Βοβορύγμια*, I grumble).—Rumbling sounds produced in the abdomen by the movements of gas within the bowels or stomach.

BORDIGHERA in Italy, on the Riviera. A suitable winter residence for patients suffering from some forms of chest-disease. The climate is warm and dry. See CLIMATE, Treatment of Disease by.

BOTHRIOCEPHALUS (*Βοθριοκέφαλος*, a pit, and κεφαλή, the head).—A genus of cestuæ entozoa characterized by the possession of two pits or depressions, one on either side of the head, in place of the four sucking disks usually present in tapeworms. The reproductive openings, instead of being placed along the margin of the so-called joints or segments of the body, occur at the ventral surface along the mesial line. Three species of *Bothriocephalus* are known to infest the human body. These are the broad tapeworm (*B. latus*), the Greenland tapeworm (*B. cordatus*), and the crested tapeworm (*B. cristatus*) recently described by Davaine. From a clinical point of view little need be said concerning them. The broad tapeworm is rarely seen out of Europe, and then only, it would seem, in persons who have travelled on the Continent. It is most common in Switzer-

land and north-western Russia; but cases also occur in Poland, Sweden, Holland, Belgium, the south-western provinces of France, and sometimes in Ireland. In reference to treatment, the parasite readily yields to the remedies employed in ordinary cases of tapeworm. In English practice we have generally resorted to male fern, but Dr. Arthur Leared has found kama equaly efficacious. See TAPE-WORM; and TENIA. T. S. CONNOLD.

BOTS.—A term employed to designate the larvae of certain dipterous insects called gadflies. They more rarely infest man than animals. See CE-STRUS.

BOULIMIA. See BULIMIA.

BOURBONNE-LES-BAINS in France. Common salt waters. See MINERAL WATERS.

BOURBOULE, I.A. in France. Thermal saline and arsenical waters. See MINERAL WATERS.

BOURNEMOUTH in Hampshire. Regarded as a suitable winter residence for patients suffering from certain forms of chest-disease. The climate is mild and slightly humid. See CLIMATE, Treatment of Disease by.

BOWELS, Diseases of. See INTESTINES, Diseases of.

BRAIDISM.—SYNON.: Hypnotism.—Braidism is the name which, after its inventor, James Braid, has been applied to a therapeutic method destined to utilise the undoubted powers of mind over body for the cure of various diseases. In essence it consists of a species of Mesmerism, the patient being reduced to a partial or complete trance-like condition, by being made to look fixedly for a few seconds at a bright object held by the operator at 'about eight to fifteen inches above the eyes, at such a distance above the forehead as may be necessary to produce the greatest possible strain upon the eyes and eyelids, and enable the patient to maintain a steady fixed stare at the object.' The patient must be made to understand that he is to keep his eyes steadily fixed on this object, and his mind riveted upon the image of it. After no short a time as ten or fifteen seconds some patients may be intensely affected, and if so, it will be found, on gently elevating the arms and legs, that the patient has a disposition to retain them in the situation in which they have been placed. 'If this is not the case,' Mr. Braid writes, 'in a soft tone of voice desire him to retain the limbs in the extended position, and thus the pulse will speedily become greatly accelerated, and his limbs in process of time will become quite rigid and involuntarily fixed.' By slightly prolonging this process a condition of profound 'nervous sleep' may be induced, in which operations may be performed as easily and in as painless a manner as if the patient had been under the influence of chloroform. All this has been abundantly proved by Esdaile and others who performed numerous operations upon Hindoos, with absence of all pain, whilst they were in the hypnotic state. In his attempts to cure morbid conditions, however, Braid only rarely succeeded so far as to induce actual unconsciousness. Whilst in a semi-cataleptic condition the patient's attention is strongly directed to the

morbid part, and some very marvellous instances of relief are recorded by him, said to have been effected under the influence of this faculty only, without the aid of imagination, since some of the patients operated upon were quite incredulous as to any good being likely to result. In a recent work on 'The Influence of the Body upon the Mind,' Dr. Daniel H. Tuke remarks: 'Braidism possesses this great advantage, that while the Imagination, Faith or Expectation of the patient may be beneficially appealed to, this is not essential; the mere concentration of the attention having a remarkable influence, when skilfully directed, in exciting the action of some parts, and lowering that of others. The short period of time required, also, compares favourably with that consumed in some other forms of mental therapeutics. . . . The great principle which appears to be involved in all is the remarkable influence which the mind exerts upon any organ or tissue to which the Attention is directed, to the exclusion of other ideas, the mind gradually passing into a state in which, at the desire of the operator, portions of the nervous system can be exalted in a remarkable degree, and others proportionately depressed; and thus the vascularity, innervation, and function of an organ or tissue can be regulated and modified according to the locality and nature of the disorder.' Braidism certainly deserves more attention than it has received, though it is a method very difficult of adoption in ordinary practice, and which, however legitimate may be its foundations, would, unless the greatest care and vigilance were exercised, be apt to descend perilously near to the level of quackery. Still, if only half the results which have been attributed to Braidism would follow the systematic adoption of this method for the alleviation of many diseases, it is one which should commend itself to the earnest attention of future enquirers who may be able to place the practice upon a broader and firmer foundation than that on which it now rests. See MESMERISM.

H. CHARLTON BASTIAN.

BRAIN, Diseases of.—General Observations.—The range of unnatural phenomena which manifest themselves as the result of disturbed actions of the brain, whether from functional perturbations or structural disease, is wide and varied. This result is due to the fact that the brain, though spoken of as a single organ, is really a congeries of many distinct but functionally related parts; and further to the fact that this congeries of parts is continuous with the spinal cord and intimately related to a scattered network of ganglia—entering into the formation of the nervous system of organic life; whilst these several centres within and without the cranium are brought into connexion, through the intervention of nerves, with all other structures in the body, whether entering into the composition of the organs of relation, or into that of the visceral system.

The action of particular parts of the brain may be stimulated, depressed, or suppressed, and either of such altered modes of activity may entail a stimulation, depression, or suppression in the functions of one, two, or more distant parts of the nervous system. The first class of

effects are spoken of as *direct*, and the second as *indirect* symptoms. It is often extremely difficult, if not impossible, for us to say which of the symptoms presented by a patient suffering from organic disease of the brain should be ranged under the one head and which under the other. Our ability to make such distinctions is at present hindered by our still incomplete knowledge concerning the anatomical details of the brain, the proper functions of its several parts, and the precise modes in which they co-operate with each other.

The effects of a shock, whether produced by injury or disease, falling on such an extensive assemblage of sensitive and mutually related organs are, as may be well imagined, subject to much variation; and as a matter of fact it happens that in different cases of structural brain disease, the symptoms produced are dependent upon three factors, viz., the *situation*, the *extent*, and the *suddenness* of the lesion. Except in so far as the nature of the lesion tends to entail variations in one or other of the above-mentioned respects, it is not of much significance from a clinical point of view (i.e. it does not lead to much difference in the sets of symptoms produced) whether we have to do with a case of hæmorrhage into, or with a case of softening of the brain. Thus the 'locality' and extent of the lesion in the case of a local disease of the brain has always to be enquired into as a problem altogether apart from that as to the more or less distinct nature of the pathological change in the part affected. In other words, the problem of diagnosis in brain disease is twofold; it must have reference to the region affected (*Regional Diagnosis*) and to the pathological cause (*Pathological Diagnosis*). The causes interfering with the progress of our knowledge in the former direction are both numerous and baffling, so that, as yet, comparatively little progress has been made.

SYMPTOMS.—The most frequent effects or symptoms of functional or structural brain-disease may be thus classified:—

1. **PERVERTED SENSATION AND PERCEPTION.**—The special senses of smell, sight, hearing, touch (fifth nerve), or taste may be interfered with by diseases of their respective nerves or primary ganglia within the cranium. Owing to the decussation of the optic nerves, disease of the optic tract gives rise (most frequently) to an affection of the sight of the opposite eye. The sense of taste pertains to different nerves. Thus the glossopharyngeal has to do with this special sensation in the back part of the tongue, the palate and fauces; whilst the taste-nerves for the front part of the tongue, though they pass from these parts with the lingual branch of the fifth, seem to leave it by the chorda tympani and then proceed to the brain with the facial or the fifth nerve. Disease of the intracranial portion of the fifth nerve may not affect the sense of taste, though it impairs the common sensibility of the tongue.

Disease of the primary ganglia of these nerves, whether they are separate (first and fifth) or lodged in the brain-substance at its point of connection with the nerve, will produce decided impairment of the several special senses. But

disease of portions of the brain above these regions on one side only, even though very extensive, often exists without disturbing the exercise of the special senses on either side. There may, however, be *Illusions*, *Hallucinations*, or *Delusions* in connection with either of these senses in many functional and structural diseases of the brain, where the morbid condition is situated in parts higher up than the primary ganglia, or where there is a functional exaltation of the ganglia themselves. This latter functional exaltation seems sometimes to be favoured by morbid states of some of the viscera—especially of the stomach, or of the uterus and ovaries.

Disease in the brain may also impair the common sensibility of the body, and in some of the most marked cases, this impairment is strictly limited to one lateral half of the body (*Hemianæsthesia*). It may be very marked and last for a long time; or it may be slighter and present only for a few days. There are several modes of impressibility comprised under the term 'common sensibility.' The principal varieties are tactile impressions, impressions produced by differences of pressure and of temperature, impressions yielding pain, and lastly those of the so-called 'muscular sense.' There is, moreover, a general sensibility pertaining to the muscles and joint-textures, and the last may be profoundly impaired in some cases. The writer believes that what there is of conscious impression pertaining to that endowment known as the 'muscular sense,' is compounded of the ordinary sense of touch and pressure pertaining to the skin, plus sensations in joints and muscles accruing from the contraction of the latter.

Besides diminutions of sensibility, we often have to do with disagreeable sensations of numbness, tingling, or actual neuralgic pains in parts. The two former may be widely distributed, though neuralgia from brain-disease is principally limited to the territory of the fifth nerves.

2. **PERVERTED EMOTION AND ILLUSION.**—These manifestations vary, from the mere increased tendency to emotional displays seen in a hysterical person or in persons suffering from hemiplegia, to those more complex aberrations met with in the various forms of delirium and insanity (see *INSANITY*).

3. **PERVERSIONS OF CONSCIOUSNESS.**—Under this head may be included the comparatively rare states known as somnambulism, ecstasy, and catalepsy; as well as the exceedingly common conditions of drowsiness, stupor, and coma. The former may be said in almost all cases to be associated with functional rather than with structural disease of the brain; at least, this is most in accordance with our present knowledge. Drowsiness, stupor, and coma are, however, amongst the commonest results of organic disease of the brain (see *CONSCIOUSNESS*, Disorders of), though they are also common conditions in blood-poisoning—whether arising from fevers, æremia, or from poisonous doses of opium or of other narcotic or narcotico-irritant poisons.

4. **PERVERSIONS OF MOTILITY.**—These manifest themselves in many forms, which, however distinct they may appear to be, are, nevertheless, closely linked to one another.

Tremors may be general or local, and in the

latter case they may be most marked in the tongue and facial muscles—principally those about the corners of the mouth or the orbicularis palpebrarum. General tremors may arise from debility, over-exertion, nervousness; or they may be due to alcoholic or mercurial poisoning, or to degenerative disease about the pons and medulla, as in *Paralysis Agitans*.

Twitings may be characteristic of a highly nervous habit of body, and are especially frequent in some epileptics in the intervals between their fits, either in some of the facial muscles or in those of the neck or limbs. They may also occur in acute febrile affections, in which the functions of the cerebrum are involved, as shown by coexisting delirium, &c., and also in the course of many organic diseases of the brain. In chorea the irregular movements of different parts of the body are often of this nature; they may affect both sides of the body, or only one (hemichorea).

Spasms of a continuous or 'tonic' character are encountered in various diseases of the nervous system, such as laryngismus stridulus, trismus, hydrophobia, tetanus, hysteria, and some forms of hemiplegia and paraplegia. Such tonic spasms produce muscular rigidity, which has to be distinguished from that due to chronic changes apt to occur in paralysed limbs.

Clonic Spasms or *Convulsions* may be either unilateral or general, and may be induced by the most varied causes. When well-marked they are mostly attended by loss of consciousness, as in epilepsy and the majority of epileptiform attacks.

Co-ordinated Spasms, or movements of a struggling type, are met with in many epileptiform and hysterical paroxysms. Spasms of this type may be also limited to particular groups of muscles, as in the conjugated deviation of the eyes and neck occurring in hemiplegia, in wry-neck, in writer's cramp, and other allied affections.

Paralysis may be local and limited in seat to some of the ocular muscles, the muscles of mastication, the facial muscles, those of the tongue, or to parts supplied by the spinal accessory and pneumogastric nerve, in those cases in which there is merely an implication of the intracranial portion of one or more of the motor-cranial nerves; or it may take an incomplete or a complete *hemiplegic* type, with lesions limited to one half of the encephalon; or it may be general, and involve both sides of the body, if a large lesion exists in the pons Varolii, or if the functions of both cerebral hemispheres or their peduncles are gravely interfered with. In some of these cases, and especially with right-sided paralysis, various difficulties exist in giving expression to thoughts by means of speech or writing (see *APHASIA*). Deficient action of the will (without obvious structural change of the cerebrum) may cause paralysis in hysteria and allied states.

Defective Co-ordination of muscular acts is met with, as in stammering and in some hemiplegic defects of speech; also in the body generally in some cases of cerebellar disease, producing a peculiar and unsteady gait (*titubatio*) closely resembling that which may be met with in alcoholic intoxication. Similar motor defects

ases may be induced by vertigo of well-marked extent. Vomiting, again, is a reflex motor act due to impaired co-ordination, which occurs in many forms of brain-disease. More rarely the sphincter ani and the sphincter vesicæ become relaxed, or the bladder may be paralysed. But incontinence of feces or of urine, or inability to void the urine, are comparatively rarely met with as a result of brain-disease, except in the comatose state, or in patients who are more or less demented.

5. NUTRITIVE OR TROPHIC CHANGES.—With lesions in the motor tract of the brain in or below the corpus striatum a band of degeneration is produced, occupying part of the crus cerebri, the pons, and the medulla on the same side, and (below the decussation of the pyramids) the opposite lateral column of the spinal cord. This is one of the most important of the trophic changes occasioned by brain-disease, because the degeneration in the lateral column of the cord is apt to spread to the contiguous grey matter, and thus to give rise to some of the trophic changes prone to ensue in paralysed limbs.

Trophic changes in other organs occasioned by some severe lesions in the brain appear as low inflammations and congestions of the lungs, or as hæmorrhages into these organs; also as hæmorrhages beneath the pleura or endocardium, or even into the substance of the suprarenal capsules or kidneys.

Again, we may have acute sloughing of the integument in the gluteal region on the paralysed side, dropsy of paralysed limbs, inflammations of joints and of the main nerves of paralysed limbs, and, though more rarely, marked atrophy of paralysed muscles. Retardation or arrest of growth is also apt to occur in paralysed limbs, when we have to do with infants or young children, suffering from severe organic brain-disease.

Blanching of the hair, or altered pigmentation of the skin, also occurs not unfrequently in connection with brain-disease or violent mental emotions; whilst in the insane the nutrition of the bones and of the pinna of the ear is apt to be interfered with.

6. PERVERTED VISCERAL ACTIONS.—Exalted activity of the uterus, bladder, intestine, stomach, or heart, may be occasioned by functional brain-disturbance more especially; whilst the same brain-conditions may give rise to depressed or exalted activity of the liver or kidneys. With other functionally disturbed or emotional brain-states there may be a lowered functional activity of the salivary glands, of the heart, of the respiratory organs, of the organs of deglutition, of the organs of digestion, or of the sexual organs. These are only to be taken as mere indications of the kinds of modification that may be produced in visceral activity by brain-disease. Much doubtless remains to be learned in this direction.

It seems fitting here also to mention those contractions and dilatations of vessels which are apt to take place in different parts of the surface of the body, or in internal organs, from stimulation or contraction of vaso-motor nerves, occasioned either by direct or indirect influence exerted upon the principal vaso-motor centres in the region of the pons Varoli. These contrac-

tions or dilatations produce correlated alterations in the temperature, sensibility, and functional activity of the parts or organs affected. The temperature of paralysed parts, as well as the general body temperature, in the apoplectic state is subject to great variations, and these are now beginning to be studied more attentively. They are capable of yielding diagnostic indications of great value.

REMARKS.—Some general remarks on the subject of structural and functional diseases of the nervous system, showing how intimately these two classes of disease are related to one another, will be found in the article NERVOUS SYSTEM. Most of what is said there is applicable to diseases of the brain in particular; here, however, it is necessary to call attention to certain points specially related to brain-disease.

When paralysis occurs from brain-disease affecting one cerebral hemisphere, in the great majority of cases it is situated on the opposite side of the body, owing to the fact that the fibres conveying the volitional impulses to the muscles decussate in the medulla oblongata. It is true that many cases are on record in which the paralysis either has, or has been said to have existed on the same side as the brain-lesion. A certain number of these cases are probably due to errors either in the clinical or in the post-mortem records of the case. Others, however, still remain unexplained. The characters of the various forms of paralysis due to brain-disease are briefly set forth in the article on PARALYSIS.

Lesions of the left hemisphere much more frequently than those of the right, are associated with aphasic defects of speech; whilst, according to Brown-Séquard, lesions of the right hemisphere are more frequently and rapidly fatal than otherwise similar lesions of the left hemisphere. They are also more apt to be associated with acute sloughs of the skin on the paralysed side. Convulsions at the onset, and subsequent tonic spasms of the paralysed limbs, are also said to be more frequently associated with left than with right-sided paralysis.

Congenital atrophy of one hemisphere, or atrophy occurring in early infancy, is mostly associated with an arrest of growth and development in the limbs on the opposite or paralysed side of the body.

Very little is positively known concerning the diseases of the cerebellum. Of its functional affections we may be said to know absolutely nothing. That is, of the various functional diseases of the nervous system with whose clinical characters we are familiar we are unable to name even one which we can positively say is a functional disease of the cerebellum. Whatever the precise mode of activity of the cerebellum may be, there is a general consensus of opinion that it is principally, if not exclusively, concerned with motility, and that it has more especially to do with the higher co-ordination of muscular acts. Atrophy of one hemisphere of the cerebellum is followed by atrophy of the opposite half of the cerebellum, so that there is a strong presumption that the functional relationship of either half is with muscles on the same side of the body. Clinically we know that disease of the cerebellum is not unfrequently associated with more

or less marked paralysis on the opposite side of the body; but this effect is now generally attributed to the pressure which structural diseases of the cerebellum are apt to occasion on the pons and medulla of the same side.

ÆTIOLOGY.—The principal modes of causation of diseases of the brain may be thus summarised:—

1. *Defective Nutrition* operates by modifying the proper constitution of nerve-tissues as well as the constitution of the blood, and thereby interfering with the normal functional relations of the several parts of the brain. Anæmia, chlorosis, syphilis, ague, and all lowered states of health, however induced, and whether acquired or inherited, become predisposing or actual causes of brain-disease. To these states, favourable to the manifestation of brain-disease, should be added the various acute specific diseases, uremia, metallic poisoning, poisoning by the narcotic and narcotico-irritant poisons generally, and also by the occasional qualities of certain articles of food, such as mackerel, mussels, mushrooms, &c.

2. *Emotional Shocks* cause cerebral disorder, especially in children, or prolonged overwork in those who are older—particularly when combined with worry and anxiety, with sexual excesses, or with protracted lactation. Religious excitement, again, not unfrequently leads to insanity.

3. *Physiological Crises*, such as the period of the first dentition, the period of puberty, pregnancy, and the climacteric period, all favour the manifestations of various nervous diseases.

4. *Visceral Diseases* or surface-irritations (especially in children or in persons having a very sensitive and mobile nervous system) may give rise to varied nervous diseases. Thus we may have convulsions or delirium in children from the presence of worms or other irritants in the intestines, or convulsions in adults during the passage of a renal calculus. Again we may have the phenomena classed as hysteria, or we may have nymphomania, in consequence of certain states of the sexual organs. Cases of paralysis are said also to have a reflex origin occasionally, though this must be a very rare event. With much greater frequency we find surface-irritations of various kinds leading, as in Dr. Brown-Séquard's guinea-pigs, to epileptiform attacks.

5. *Structural lesions* of the brain itself give rise to a very large proportion of its diseases. The various kinds of change will be found enumerated under another heading (*see* NERVOUS SYSTEM) Hæmorrhage and softening are the most common and, therefore, the most important of these morbid conditions.

6. Brain-disease may be determined by the action of *Heat (insolatio)*, especially when combined with fatigue and deficient aëration of blood. A somewhat similar brain-affection, however, is occasionally developed in the course of rheumatic fever or in that of one of the specific fevers, in which the body-temperature rapidly rises to a lethal extent (100°–111° F.).

7. *Concussions* (whether from blows or falls) may give rise to brain-disease, even where no traumatic injuries or lacerations of the brain are produced.

TREATMENT.—The treatment of brain-disease

will be discussed under the articles NERVOUS SYSTEM, PARALYSIS, CONVULSIONS, and those on the several special diseases which will now be described in alphabetical order.

H. CHARLTON BARTMAN.

BRAIN, Abscess of.—This term is applicable whenever a circumscribed collection of pus is formed in any part of the cerebral mass.

ÆTIOLOGY AND PATHOLOGY.—Amongst the most frequent causes of cerebral abscess are severe injuries to the skull, disease of the temporal bone in connection with the ear, ligature or obstruction of a main artery, and pyæmia. Under the three first-named conditions the abscess is usually solitary, but from pyæmia multiple abscesses often result. For practical purposes we may perhaps conveniently discard the latter—since the symptoms will usually be those of general encephalitis—and confine ourselves to those cases in which single large-sized collections of pus are met with. With this limitation, abscess in the brain is by no means of frequent occurrence.

The best marked, and also the more common examples of large brain-abscess are met with in connexion with compound fractures of the skull, and by far the most definite symptom which denotes them is the formation of a fungus cerebri. Unless in a compound fracture the brain be directly injured and the dura mater torn, it is very rare indeed for any suppuration in its substance to occur. It is not to be denied, however, that now and then, after severe concussion or laceration without external wound, abscess may follow. In such cases we may conjecture that usually some slight laceration or extravasation occurred in the first instance, which constituted a focus for the inflammation. Abscess after simple concussion without lesion is probably a most rare event.

In the article BRAIN, Inflammation of, we shall have to define Encephalitis as a diffuse change of a large part of the cerebral mass, perhaps of a whole hemisphere, attended by the infiltration of cells and fluid. It is obvious that the term abscess in the brain is applicable to one of the results of encephalitis, but it seems clinically probable that the two classes of cases are for the most part distinct, and that diffuse encephalitis has but little tendency to result in abscess, and that abscess is rarely preceded by a stage of encephalitis. Both are usually the consequences of local injury to the brain, or of extension from local disease of its coverings; but whilst encephalitis probably resembles the erysipelatous type of inflammatory action, in localised abscess this tendency is not present. Having distinguished brain-abscess from encephalitis, we must next say a word as to the risk of confusing it with intra-cranial but extra-cerebral collections of pus. Encysted collections of matter may be met with either between the dura mater and bone; or within the arachnoid cavity; and perhaps it ought to be added, though with some hesitation, beneath the arachnoid, in the pia mater. Not unfrequently inflammation of the membranes precedes and attends the formation of an intra-cerebral abscess, and in these cases the symptoms will be mixed. In dealing with published cases it is also necessary to be on our guard as to certain errors which have arisen

in—cases of meningeal abscess being spoken of as *ura-in*-abscess. Mr. Prescott Hewett has expressed his opinion that the celebrated case of *le la Peyronié* was an example only of extra-cerebral abscess. It is absolutely necessary to make these restrictions if we would judge correctly as to the symptoms which attend local collections of matter in the brain and the usual terminations of such cases.

SYMPTOMS.—The symptoms of local suppuration in the brain will vary with the stage, the size of the collection, its precise situation, and, above all, with the presence or otherwise of a fistula of relief. In many of the cases which come under surgical care a fistula exists from a very early period, though not unfrequently it is liable to occlusion. Under the latter conditions the symptoms of a closed and an open cerebral abscess may be alternately studied in the same case. It will usually be observed that when the exit is closed and the abscess fills, the patient complains more or less of headache, becomes heavy and drowsy, experiences twitchings or spasms in the opposite side of the face and limbs, with some tendency to hemiplegia. Of this group the tendency to spasms is probably by far the most significant. The headache may be but trifling, and the patient may even be well enough to leave his bed, when the occurrence of spasm followed by paresis alone gives warning of what is going on. The cases now alluded to are chiefly those in which abscess results from compound fracture of the skull with laceration of the brain-substance. In these the abscess often gives way spontaneously, and a fistula forms, around the orifice of which a mass of poulticing brain-granulations, known as *fungus cerebri*, usually forms. In these cases the canal of communication may be very tortuous, and the liability to blocking considerable. Now and then the same result may be met with after syphilitic disease of the skull and meninges. The writer had some years ago a man under his care in whom he had opened a cerebral abscess beneath a hole in one parietal bone. The patient was able to walk about, and ailed but little so long as the fistula was freely open; but spasms of the face, or even convulsions of the limbs (on the opposite side) always followed its occlusion. The softening gradually extended, and he at length died in consequence, perhaps, of the impossibility of making a counter-opening in a depending situation. Unless the abscess be in the anterior lobe, there will almost invariably be present some degree of hemiplegia, but this will of course vary with the size of the collection and the extent of destruction of tissue. The formation of an abscess after injury is sometimes very insidious, the symptoms being very slight. The cases in which violent headache and pain, vomiting, delirium, and dry tongue, are said to have been present in the early stages are, the writer suspects, usually instances of suppuration between the bone and dura mater. These symptoms occur especially when brain-abscess follows disease of the internal ear, and in these there nearly always is the complication of inflammation around the petrous bone. Such symptoms are very rarely present in traumatic abscesses, which often develop very quietly until they attain a considerable size. It is pro-

bable that some degree of rigor, attended by rise of temperature, usually occurs in the beginning of cerebral abscess, but no very precise data are extant on these points.

The contents of a brain-abscess usually consist to some extent of broken-up cerebral tissue, and in some cases there are but very few pus-cells. Especially is this likely to occur when the so-called abscess follows on ligature of the carotid or occlusion of a cerebral artery. In these cases, it is in the first instance at least the result of a process of softening rather than of true suppuration.

If a large abscess be permitted to develop without relief, the symptoms of compression will in time ensue: first spasm, then hemiplegia, then hebete and coma, preceded possibly by violent convulsions.

DIAGNOSIS.—The diagnosis between cerebral abscess and meningeal abscess is exceedingly difficult, and often a guess is all that can be made. The almost invariable occurrence of spasm or convulsions in the former, and their frequent absence, with the greater degree of pain and headache in the latter, are the most reliable signs. Sometimes—as, for instance, when trephining has been practised, and no inflammatory products are found between the bone and dura mater or under the latter—the diagnosis may be helped by this negative knowledge. In such cases, if hemiplegia, preceded by spasm, have been gradually developed, the surgeon will be well justified in making an incision or puncture into the hemisphere. Optic neuritis may equally be present in both, and its presence or absence will scarcely help the diagnosis.

PROGNOSIS.—In addition to the danger of death by compression, there is the risk that the abscess may break into the ventricles or into the subarachnoid space. Some cases are on record in which spontaneous openings into the nose or into the ear occurred, and profuse discharge followed, the patient in the end recovering. It may be doubted whether these were not instances of meningeal abscess.

TREATMENT.—It is needless to say that if abscess be diagnosed with any degree of confidence an opening is essential. There is little or no room for medical treatment. For the prevention of abscess, in all cases in which injuries likely to produce it have occurred, the utmost precautions should be enforced. Mercury in small doses, frequently repeated, should be given from the first; the injured region should be covered with lint soaked in a strong spirit-of-wine lotion, frequently re-wetted; purgatives should be administered; and the patient should be kept very quiet until long after the healing of the wound.

JONATHAN HUTCHINSON.

BRAIN, ANÆMIA OF.—**DEFINITION.**—A condition in which the blood contained within the capillaries of the brain is deficient in quantity, or defective in quality.

The blood within the brain is contained in arteries, capillaries, and veins. The functional condition of the brain depends on the quantity and quality of the blood circulating in its capillaries, and it is to these that the special symptoms are related. Deficiency in the quality of the

blood supplied to the brain is always of gradual occurrence, and affects the whole brain: deficiency in quantity of blood may affect the whole brain or part only, and it may be sudden or gradual in its production.

ÆTIOLOGY.—*General cerebral anemia* may be due to the following causes:—(1) It may be a part of systemic anemia—defect in quantity or quality of the whole blood, and due to causes which are considered elsewhere. This is often seen in cases of hæmorrhage, of exhausting discharges, or of defective blood-nutrition, as in chlorosis. (2) The supply of blood to the brain may be deficient, the quantity of blood in the body being normal. This may be due to cardiac weakness, or to causes acting through the nervous system on the heart, as in swooning. In systemic anemia, the lessened cardiac power increases the cerebral deficiency. Whatever lessens the amount of blood discharged from the heart at each systole, such as aortic or mitral disease, may be a cause of cerebral anemia. Pressure on the vessels conveying the blood to the head, as by an aortic aneurism, has a similar effect. Unequal distribution of the systemic blood is another cause. The intestinal vessels, if dilated, are capable of containing a large part of the blood of the body, and the effect of their engorgement is often seen after paracentesis abdominis. One theory of shock ascribes its mechanism to vaso-motor dilatation of these vessels, and consequent anemia of the rest of the system. The effect of such cause is increased by the action of gravitation in the erect posture. Some causes act only in that position. (3) The capacity of the cerebral vessels may be diminished by pressure on the brain, exerted by effusions of fluid (hydrocephalus), of blood (in cerebral and meningeal hæmorrhage), or by growths within the skull.

Partial cerebral anemia is due to some obstruction to the passage of the blood through the vessels. To be permanently efficient such obstruction must be situated beyond the circle of Willis. Ligature of one carotid causes immediate symptoms of cerebral anemia, but permanent symptoms are not frequent. Pressure on, or disease of one carotid, for the same reason rarely gives rise to symptoms. Obstruction in certain arteries of the brain may cause local anemia, sudden or gradual, temporary or permanent, according to its cause. Such obstruction may be due to narrowing of the calibre of the vessel by atheromatous changes in its wall, or by spasm of its muscular coat, or may be due to actual occlusion by embolism or thrombosis. The pressure-effects of an intruding substance within the skull (tumour, or clot) act most intensely in, and may influence only one region of the brain.

It is obvious that of these causes some act suddenly, others gradually, and the symptoms produced will differ accordingly.

ANATOMICAL CHARACTER.—The principal anatomical character of cerebral anemia is pallor of the brain, observable chiefly in the paler tint of the cortical substance, and the diminished number of red spots in the white centre. The pallor may be partial or general. The membranes are usually pale, but in some cases of partial anemia they are hyperæmic. Effusion

of serum in the meshes of the pia mater and between the convolutions, may be found in general anemia.

SYMPTOMS.—The symptoms of this condition vary according as the anemia is suddenly or slowly produced, and as it is general or partial.

(1) In *sudden general anemia* of the brain the sufferer feels drowsy; the special senses are dulled; noises in the ears and vertigo are complained of; the pupils are at first contracted; sight may fail; muscular power is weakened; respiration is sighing; the skin is pale, cold, and moist; nausea is common; and headache is rare. If the anemia is more intense, consciousness is lost; there is universal paralysis; and general convulsions may occur, epileptiform in character, these being especially frequent in sudden extensive losses of blood in strong subjects. The pupils dilate, and the coma may deepen to death. The loss of sight in cases which recover may persist as permanent amaurosis.

(2) When general anemia of the brain is *slowly* produced, the state of the cerebral functions is usually that of 'irritable weakness.' Their action is imperfect in degree, and excited with undue facility. There is mental dulness and drowsiness; sometimes, however, insomnia is troublesome. Delirium is common in severe cases, and is conspicuous in some forms of imperfect blood-nutrition, as in the so-called 'manic delirium.' Headache, usually general, is a common symptom. Sensory hyperæsthesia, tinnitus, muscæ volitantes, and vertigo are frequent. Convulsions are rare, but muscular power is generally deficient. All these phenomena are more marked in the erect than in the recumbent posture, especially when the erect posture is suddenly assumed. It has been remarked that some anæmic persons can think well only when lying down. In young children, after exhausting discharges, as diarrhoea, symptoms referable to cerebral anemia are common, namely, somnolence and pallor, with depressed fontanelle and contracted pupils. The somnolence may deepen to coma with insensitive conjunctiva, and the coma increase to death. Such symptoms have been called *hydrocephalic*, from some resemblance to those of acute hydrocephalus.

(3) *Partial cerebral anemia* causes, if complete, loss of function in the affected area; and if it be permanent, as in obstruction of a vessel beyond the circle of Willis, necrosis of the cerebral tissue results (see BRAIN, Softening of). If incomplete and sudden, there is temporary arrest of function. Ligature of one carotid, for instance, causes transient weakness and numbness in the opposite half of the body. There may be at first an over-action of grey matter, causing, in certain regions, unilateral convulsions. If *slowly developed*, as in atheroma of arteries, pain and vertigo are common, with recurring local symptoms, such as numbness, tingling, and weakness.

In all cases of long-continued cerebral anemia, permanent damage to the nutrition of the brain may result. In the child the development of the brain may be arrested; in the adult, loss of memory and of general mental power indicate the deterioration of structure.

PATHOLOGY.—The symptoms are, as already stated, dependent mainly on the defective quantity

and quality of the blood circulating in the brain. Some influence may probably be ascribed to the diminution in the blood-pressure to which the nerve-elements are ordinarily exposed (Burrows). Nothnagel has pointed out that the symptoms indicate an early affection of the respiratory centre in the medulla, and of the cortical grey matter. Kussmaul and Tenner ascribe the convulsions in acute anæmia to the irritation of the medulla; Nothnagel, to that of the pons Varoli.

Diagnosis.—The diagnosis is not difficult. It rests on the recognition, in a given case, of the causes of cerebral anæmia; and on the exclusion of graver maladies, as organic cerebral disease. With the latter, it should be remembered, anæmia of the brain, local or general, often co-exists. Some symptoms of hyperæmia of the brain closely resemble those of anæmia. A common pathological state of imperfect blood-renewal probably exists in both conditions.

Prognosis.—The extent to which the cause of the anæmia is amenable to treatment, and is of transient character, must influence the prognosis. As a rule this is favourable when there is no organic disease of heart, vessels, or brain. In the so-called 'pernicious anæmia,' the prognosis is, of course, unfavourable. Hydrocephaloid symptoms in infants, if met by prompt and suitable treatment, are usually recovered from.

Treatment.—The treatment necessarily varies in the several forms of the affection, but it is in the main causal. The beneficial effect of the recumbent posture in affording immediate relief to the symptoms, and obviating permanent damage to the cerebral nutrition, must be always remembered. In acute anæmia from loss of blood, the head must be kept continuously low, stimulants freely administered and as a penultimate resort landages applied to the limbs from below upwards may increase the proportionate supply of blood to the brain. If this fails transfusion must be had recourse to. In chronic anæmia sudden change of posture should be carefully avoided, and ferruginous tonics are needed. In spasm of the cerebral vessels, bromides are useful. In the cerebral anæmia of syncope, the recumbent posture, stimulants to the skin, cold water, faradisation, sinapisms, and ammonia to the nasal mucous membrane, assist the recovery of cardiac action and the return of consciousness. In all cases, carefully regulated food and stimulants are needed; beef-tea should be given in small quantities, at frequent intervals. The group of symptoms called hydrocephaloid require similar treatment.

BRAIN, Aneurism of. See **BRAIN, Vessels of, Diseases of.**

BRAIN, Atrophy of.—Atrophy of the brain may be congenital, due to arrest of development in very early fetal life; or the constituents of the brain may have been perfectly developed, and may subsequently disappear from one of several causes. This morbid state is regarded as primary when there has been no pre-existing disease of the brain or its membranes; secondary, either when there has been such pre-existing disease, and the atrophy has occurred from absorption of the part broken down by inflammation, softening, hæmorrhage, &c.; when

atrophy of some special cerebral organ follows upon destruction of the particular nerve that arises from it; or when localised atrophy has taken place in a very gradual manner from pressure of a tumour, of ventricular effusion, &c. To take these forms in order:—

1. *Congenital atrophy.*—This is usually associated with weakness of intellect, even to the extent of idiocy; there is atrophy of the body opposite to the side of the cerebral lesion, and this atrophy involves all structures, even the bones. Paralysis of various intensity supervenes, often with contraction of the paralysed parts; there being no particular sensitiveness of the special senses, possibly because of the mental hebetude. Epileptic attacks are common; vitality is low; and the patient easily succumbs to other diseases.

2. *Primary atrophy.*—In this variety there is general diminution both of volume and of weight, affecting most usually the cerebral hemispheres, and that in pretty equal degree. It is most common as a condition of old age—*sensile marasmus, atrophica cerebri senilis*. It sometimes in earlier life follows exhausting diseases; and may also be caused by deficient or impure blood-supply to the brain. In close connexion with this mode of causation it is seen after repeated attacks of intoxication, especially after delirium tremens. In this last condition the cerebral atrophy may be acute and rapid.

3. *Secondary atrophy.*—This may be general or partial. When general, the convulsions have a shrunken appearance, and there is always an increase of the subarachnoid fluid. This condition follows various lesions of the brain, especially of the convex surface, such as hæmorrhage of the convexity, encephalitis, or more accurately that form of encephalitis that attacks only the grey matter or perhaps only one layer of the grey matter, as in some mental diseases. When the atrophy is partial, there are found depressions in an otherwise normal hemisphere, at which point a localised hæmorrhage or patch of softening, inflammatory or depending on thrombosis or embolism of vessels, has been absorbed, leaving only a cavity of greater or less extent, filled with fluid and sometimes lined with a thin membrane. A certain portion also of the brain may become atrophied by the gradual pressure of a tumour or any foreign body. Even the little sieve-like depressions seen in various situations after constantly repeated congestion of vessels may be the result of atrophy from compression by the distended vessels. Functional inactivity and atrophy of the optic nerves has led to a similar abnormality of the corpora quadrigemina.

ANATOMICAL CHARACTERS.—The atrophied brain or portion of brain will vary in appearance on minute examination, according as the lesion has or has not been preceded by inflammation. When the atrophy is primary and due to gradual interference with blood-supply, there is seen a shrunken condition of the nerve-tissue, especially of the calibre of the nerve-tubes. The cells are smaller than usual and pigmented, the arteries being decreased in size or themselves diseased. If the lesion has had an inflammatory origin, the process in order of sequence is, first, inflammation, then softening with fatty degeneration, then partial absorption, and so atrophy;

the appearances differing according to the stage of the lesion. Traces of fatty degeneration of all the tissues,—vessels, nerve-tubes, and cells,—may be found, with the neuroglia either wanting or sclerosed.

Dr. Rudolph Arndt has lately thrown doubt on the possibility of determining atrophy of the ganglionic bodies or nerve-tubes by their size. The size of these bodies varies so greatly, within the limits of health, that he considers this test a very uncertain one. Almost the only trustworthy sign of atrophy, in his opinion, is the appearance in the substance of the ganglionic bodies and in the medullary sheath of nerve-bundles, of black shining globules, somewhat fatty-looking. In process of time these globules increase in number, and at last the whole of the bodies appear permeated by them. These globules are not fatty, they are certainly more or less pigmental. Exactly similar bodies appear at post-mortem examinations, and are a sign of simple decomposition. The duration of this condition, irrespective of pre-existing lesions, is protracted.

SYMPTOMS.—The symptoms of atrophy of the brain necessarily vary according to the seat, extent, and ætiology of the lesion. Primary atrophy of the cerebral hemispheres and the first form of secondary atrophy will most usually induce imbecility, or some lesser degree of mental insufficiency, loss of memory, slowness of thought, and other mental diseases. Headache, giddiness, delirium, and stupor are seldom met with. Interference with speech is more common. Affections of sight, and of the motor condition of the eye, do not depend on general atrophy of the brain; they own a more local cause.

Convulsions, paralysis, stiffness of muscles, or contractions are often met with in connexion with this general lesion, as well as various irregularities of locomotion: but it must be remembered that general atrophy of brain is not seldom associated with atrophic or sclerotic lesions of the spinal cord, and even where this is not so, several of the morbid phenomena, and particularly convulsion and paralysis, may derive their origin, not from the atrophy, but from the condition pre-existent to the atrophy, such as hæmorrhage of the convexity, meningitis, or peri-encephalitis.

In secondary atrophy of a more limited extent, the symptoms are apt to be more strictly localized, such as partial loss of power in a single limb, slight imperfections of speech, or strabismus; but here again the positive diagnosis of atrophy is hindered by the complication of pre-existent disease, the local congestions, hæmorrhages, softenings, tumours, or other conditions of which the atrophy is only the sequence. Still less characteristic are the phenomena attending general or partial atrophy of the cerebellum, the pons, and the medulla oblongata.

TREATMENT.—Treatment is useless as to the atrophy of the brain: it must be directed to supporting the powers of the patient.

E. LONG FOX.

BRAIN, Carcinoma of. See **BRAIN, Tumours of.**

BRAIN, Compression of.—The brain is compressed in the pathological sense whenever its

structure is so squeezed that its functions are in any degree interfered with. This squeezing may be effected either by the effusion of blood within the skull, the growth of a tumour, the accumulation of pus or serum, or lastly by the depression of some large portion of the bony parietes. The general belief that depressed fractures are frequently the cause of compression is probably quite a mistake. In such cases the fragment displaced is rarely of sufficient size to cause serious compression of the contents of the skull, and the symptoms usually supposed to indicate that state are really due in most cases to laceration and contusion, or to subsequent inflammation. This point is of great importance in practice, for upon its recognition depends much of the validity of the reasoning by which the operation of primary trephining in compound fractures is defended or condemned. It also offers a most serious fallacy as regards the interpretation of the symptoms due to compression.

By far the best examples of uncomplicated compression of brain are supplied to us by the not very infrequent cases in which a middle meningeal artery is injured, and a large blood-clot is effused between the dura mater and bone. It is from observation of cases of this kind that the assertion is justified, that a very considerable intrusion into the skull is permitted without the production of any symptoms. No doubt the suddenness or otherwise has much to do with the results, but there seems good reason to believe that, as a rule, the brain will easily accommodate itself to quantities not exceeding an ounce or two, and that usually so large a quantity as four or five ounces is required to cause death. It is very rarely indeed that a depression of bone in the least approaches such an extent of intrusion as this, and the majority of such cases are, as regards the amount of possible squeezing, quite trivial. The manner in which the accommodation is effected is by the removal of the fluid contents of the skull, first the subarachnoid fluid, and secondly the blood. Of the blood-vessels the veins and venous sinuses are probably emptied first, and lastly the arteries and capillaries. A brain in a state of strong compression is an exsanguined brain. In this respect, the brain in the last stage of compression differs very much from that in cases of insensibility from concussion or contusion. It by no means follows that because the brain is pale, the face should be pale also; but it is perhaps usually the case that extreme compression so much enfeebles the heart's action that the pulse is weak or flickering, the respiration shallow and irregular, and the skin pale and cold. That stertorous breathing, a laboured pulse, and a suffused and dusky countenance, are (as according to the classical description) symptoms of compression, is probably for the majority of cases a mistake. Such a group much more frequently denotes laceration, contusion, or central extravasation. Nor is it true that hemiplegia, excepting of the most transitory kind, is often due to compression. A clot of blood poured out over one hemisphere may, if rapidly effused, produce for a while weakness of the opposite limbs, but the brain mass is soft enough to allow of considerable yielding, and in the course of a few hours the

effects of the displacement will have become general, and not local. In a case recorded by the writer in which a post-mortem, some weeks later, proved the presence of a large blood-clot, there had been partial hemiplegia without unconsciousness at first, but on the next day all trace of it had disappeared, and it never returned. In many of the cases of bleeding between the dura mater and bone, from the meningeal artery, the hæmorrhage takes place on several different occasions, with, it may be, intervals of a day or two, much as is often observed in wounds of arteries, such as the palmar arch. Thus the observer is able to appreciate the symptoms caused by different degrees of compression, and further proof is afforded that, if the intruded quantity be but moderate, the brain bears it without obvious inconvenience. Often at the autopsy it is quite easy to distinguish clots of very different dates, and to feel sure that the original one was of considerable size. It is clear then that in speaking of the symptoms of compression we must allow for differences in amount of the compressing substance, and also for differences in the rapidity or suddenness of its application.

When compression is produced instantaneously, as by a large fragment of bone driven down, the case is almost invariably complicated by contusion. If paralysis or even insensibility be present, it is usually impossible to say to which lesion they are really due. We may, however, hold it almost certain, from what we know of other cases, that the effects in such would be a temporary hemiplegia, with symptoms of shock if the depression were but moderate; and insensibility, probably soon followed by death, if the depression were very great. The cases in which depression of bone has alone been sufficient to produce long-continued compression with insensibility are possibly somewhat apocryphal. It is possible that compression under such circumstances might be attended by stertor and laboured pulse, but it is possible also that the pulse might be extremely feeble, the countenance pale, and inspiratory efforts weak and irregular.

The depression of bone is perhaps the only condition which can be supposed capable of producing compression suddenly. When blood is poured out from a ruptured artery, the symptoms come on rather gradually. The patient complains perhaps of headache, and then becomes more or less confused in manner, his gait is unsteady, and the limbs on the side opposite to the injury show special weakness. Vomiting may occur and the weakened limbs may twitch, and unless, as is often the case, the intracranial bleeding stops, these symptoms are soon lost in a state of complete insensibility, with pale face, feeble pulse, and symptoms of shock. Convulsions may now occur, and death often supervenes very quickly. In such a case the whole course of the symptoms may occupy less than an hour. The surgeon ought, of course, to trephine and let out the blood, and he must be prompt, or his patient may die during his preparations. More commonly this rapid termination occurs unexpectedly after one or more previous attacks of temporary head-symptoms, and the patient may have appeared quite well in the intervals. In

cases in which the symptoms progress without interruption, their rapidity, no doubt, depends upon the size of the vessel ruptured. Certain special symptoms will also depend upon the precise position taken up by the clot which may chance to press upon special nerve-trunks as well as upon the brain-mass. In ordinary cases the clot is beneath the squamous bone and the lower part of the parietal, and passes downwards into the sphenoidal fossa. In the latter region it may press upon the nerves going to the sphenoidal fissure; and it is of importance for the surgeon to know that dilatation of the pupil on the affected side is often produced. This important symptom is probably due to pressure upon the third nerve.

There is yet another class of compression-cases in which that condition is produced by the slow accumulation of the products of inflammation within the skull. Much will depend, as regards special symptoms, upon the position of the abscess, either within or without the brain. If in the substance of the brain, it must more or less disorganise its structure, and thus cause symptoms due to laceration as well as compression. Under such conditions some degree of hemiplegia, with, probably, preceding spasms of limbs, can scarcely fail to be present. Now and then cases occur in which an irregular sinus leads into an abscess-cavity in the brain, and this sinus being sometimes free and sometimes blocked, the surgeon has repeated opportunity of estimating the effects of filling of the cavity. In such cases, headache, stupor, unilateral twitching of limbs, partial hemiplegia, with, perhaps, vomiting, and, it may be, general convulsions, are the symptoms to be expected. The position of the abscess as regards different regions of the brain is also of much importance, but its discussion cannot be entered upon in any detail here, and it obviously concerns rather disorganisation of structure than simple compression.

When a large accumulation of pus takes place between the bone and dura mater, the symptoms produced are much the same as those caused by blood-clot. We must make, however, much allowance for the fact that these cases are almost always attended by meningitis, and thus the symptoms of compression are masked by those due to inflammation. Chronic abscess under the bone without arachnitis may occur now and then in syphilitic and other disease of the skull-bones, but such cases are very rare. Such cases will differ from those of hæmorrhage in that the symptoms are always produced very slowly. The writer once had the opportunity of watching such a case, in which the patient died of compression, very gradually produced, and without any complication. The chief symptom was constant wearing headache, which prevented sleep. The man was pale and feeble, but not paralysed in any part, excepting that both eyelids drooped. He was rational, but spoke slowly, as if in a state of partial stupor. During the last two or three days of life he had convulsions, and finally, for twenty-four hours, he was in a state of increasing insensibility.

DIAGNOSIS.—It will be seen from what has been said above that the diagnosis of compression by symptoms is exceedingly difficult, and that

the utmost use must in each case be made of the history of the case. In those of blood-compression after injury to a meningeal artery, there is almost always the fact that the patient between the date of the injury and the superposition of symptoms had an interval during which there appeared to be little or nothing the matter. This history is, if the symptoms have developed rapidly and without the signs of inflammation, by itself conclusive for diagnosis. Under such conditions trephining ought to be at once resorted to, or possibly it might be yet better practice to first tie the carotid artery.

The diagnosis of abscess in the brain-substance has already been discussed, and that of inflammatory collections from meningitis will be examined in its proper place (see *MEINGITIS, Diseases of*).

TREATMENT.—The treatment of compression of the brain is almost wholly surgical, and consists in the use of the trephine and knife to elevate depressed bone, or evacuate collections of blood or pus. JONATHAN HUTCHINSON.

BRAIN, Concussion of.—We class under the head 'Concussion of Brain' all symptoms which result simply from the shaking, more or less violently, of the contents of the skull. It will be obvious, however, that most cases of severe shake of the brain are likely to be complicated by visible lesions. The skull may be broken and the brain may be contused, lacerated, or ecchymosed. It is highly probable, however, that well-marked and even serious symptoms may be produced by shaking only, and without the existence of any lesion discoverable either by the unaided eye or the microscope. We must further clearly understand that this element of concussion (*sic* the results of shake independent of lesion) enters into almost every case of injury to the head. Whatever be the other lesions, it is usually the fact that the brain has been more or less severely shaken. Thus it may easily happen in cases in which conspicuous lesions are present, such as fracture of the base or local contusion, that still the results of the shake are the most important. It might be convenient if we were in the habit of speaking of most cases of severe injury to the head as *Concussion plus other lesions*, with the endeavour to assign to each added complication its proper share in the general result. These explanations are necessary before we put the question—Can concussion alone cause death? Although it is highly probable that we ought to reply with a very confident affirmation, and to assert that it is very common for concussion to be the chief cause of the fatal event, yet it is very difficult to prove it, since the cases are extremely rare in which severe concussion is produced without some attending lesion. The symptoms caused by concussion of the brain may be studied in very numerous cases of very various degrees of severity, which yet recover perfectly. From what is observed in these, we may infer as to the part which concussion takes in complicated cases many of which prove fatal.

The results of concussion may be divided into three stages—the first stage is that of *collapse*; the second, that of *reaction*, or of vaso-motor paresis, or, if named from its most prominent

symptom, the *sleepy stage*; the third is that of *convalescence*, or recovery. The symptoms of the first stage, or stage of collapse, vary with the severity of the case, but if at all well-marked consist in feebleness of pulse, pallor of skin, coldness of extremities, and dilatation of pupils. They may approach a condition which threatens immediate death. There is no startos, for the respiration is too feebly performed. Although the collapse may be very great, the insensibility is rarely quite complete. It is of great importance in this stage to establish the negative as regards all forms of paralysis. If any non-symmetrical symptoms are present, the case is more than mere concussion. During this stage nothing should be done, except placing the patient in a condition of comfort, and preventing the cooling of the body. Stimulants, unless the collapse is extreme, should be avoided. After the collapse has lasted some little time (half-an-hour to two, three, or more hours), it begins to pass off. The patient moans, manifests discomfort, turns on his side, and draws his knees up. Very often at this period sickness occurs, and it is almost invariable if the patient's stomach was full at the time of the accident. Consciousness is now usually restored, and, by rousing, the patient may be induced to speak, and will tell his name, &c. Gradually, during a period of some hours, the case slides on into the sleepy stage. The pulse is now relaxed and full, the skin is warm or even hot, the face may be somewhat flushed, and the pupils are contracted. The patient is overpowered with sleepiness, and can only be awakened with difficulty. It is, however, always within possibility to awaken him, and he usually rouses himself to the calls of nature. Very commonly the pulse is irregular, especially if the patient be young. At this stage again care must be taken to ascertain whether there are any non-symmetrical symptoms, any weakness of a limb, of one side of the face, or of any single eye-muscle. If the patient passes his urine or feces in bed, or if there is long-continued retention of urine, it is very probable that there is more than mere concussion—namely, laceration or contusion. The sleepy stage may last for a day or for a week, and it is in severe cases so well-marked that the patient's eyelids may be held open, and the pupils examined, without awaking him.

During this stage the measures of treatment called for are spare diet, purgation, cold to the head, and quiet. When the sleepy stage passes off, the patient is left weary, torpid, unfit for mental effort, and often with distressing headache. These are the symptoms of the convalescent stage, and they may last more or less for a considerable time. The patient should still be kept carefully quiet, no stimulants should be allowed, and purgatives should occasionally be used. Some of the symptoms present during the stage of convalescence may persist so long that they may rank rather as sequelae. Thus there may be for years nervousness, inaptitude for business, liability to headache, and peculiar susceptibility to the influence of stimulants. As a rule, however, even after very severe concussion, no such ill-results are left, but the patient regains after a time perfect cerebral health. This remark must, however, not be held to apply to

concussion when received in railway accidents; for in these cases there is a prospect of pecuniary compensation, and the sequelæ are often severe, prolonged, and very peculiar.

JONATHAN HUTCHINSON.

BRAIN, Congestion of. See **BRAIN, Hyperæmia of.**

BRAIN, Hæmorrhage into. — **SYNON.:** *Cerebral Apoplexy; Fr. Hémorrhagie cérébrale intracérébrale; Ger. Hirnblutfluss.*

DEFINITION.—Escape of blood, by rupture of a vessel, into the substance or cavities of the brain. Hæmorrhage into the meninges is separately described.

Cerebral hæmorrhage is commonly due to the rupture of an artery, very rarely to that of a vein. Occasionally, minute extravasations are caused by rupture of capillaries. Hæmorrhage from arteries or veins may also be due to their laceration by injury.

ETIOLOGY.—Arterial hæmorrhage is usually due to the coincidence of weakened vascular wall and increased pressure within the vessel. The causes of these states may be regarded as the conditions *predisposing* to cerebral hæmorrhage. Hereditary influence is sometimes distinctly seen, as a tendency to vascular degeneration, or to conditions which, as renal disease, produce such degeneration. Similarity of vascular distribution may also be inherited, and may determine the locality of strain, and, therefore, first of degeneration, and ultimately of rupture. Cerebral hæmorrhage is most frequent after fifty years of age, but occurs at any age, though rare during the first half of life. It is nearly twice as common in men as in women. It is said to be more frequent in temperate than in tropical climates, in winter than in summer, and at high than at low elevations. Certain acquired conditions act as predisposing causes. Chronic Bright's disease leads to early and extreme degeneration of vessels, as well as directly to hypertrophy of the heart and increased blood-pressure: hence it predisposes powerfully to cerebral hæmorrhage. In purpura and scurvy, cerebral hæmorrhage occasionally occurs—it is said in consequence of acute vascular degeneration and increased blood-tension. The state of vascular repletion known as plethora was formerly thought to be a frequent cause of cerebral hæmorrhage. It probably does aid other causes, but rarely co-exists with the most efficient, and so takes a very subordinate position. Chronic alcoholism and opium-eating are said to promote vascular degeneration.

The *proximate* causes of cerebral hæmorrhage are the weakened state of the wall of the vessel, and commonly some increase of blood-pressure. The vessel-wall is weakened by degeneration, and is often imperfectly supported in an atrophied brain. The increase of pressure within the vessels may be permanent, as in peripheral obstruction, with or without hypertrophy of the heart; or temporary, as in excited action of heart, or impeded circulation during effort. These causes are considered more fully in the article on **BRAIN, Vessels of, Diseases of.**

Hæmorrhage from a vein is rare, except as the result of laceration by direct injury, or of ulceration involving the vein secondarily. Varicose

veins in the pia mater may sometimes rupture (Andrill).

Capillary hæmorrhage is usually due to venous obstruction, especially to thrombosis in a vein.

ANATOMICAL APPEARANCES.—In intra-cerebral hæmorrhage, the blood is extravasated into the substance or into the ventricles of the brain—into the latter usually by rupture of a previous extravasation within the cerebral substance. In the latter situation the blood occupies a cavity formed by laceration of the brain-tissue; rarely, when very minute and 'capillary,' by merely separating the fibres. In size an extravasation varies from that of a pea or even smaller, up to that of the fist. The blood is clotted, and reddish-black in colour; and fragments of brain-tissue are mingled with it. The cavity containing it is often very irregular in shape; its walls are uneven, present projecting shreds of lacerated brain-substance, and are blood-stained and softened—at first by imbibition of serum, and later by inflammation. Many small extravasations are often seen in the neighbourhood of a larger clot. Usually there is only one large extravasation: sometimes, however, there are two or three. The extravasated blood exercises pressure; the convolutions are flattened; the sulci is bulged to the opposite side (Hughlings Jackson, Hutchinson); and the rest of the hemisphere is anæmic. The effused blood may tear its way into the lateral ventricle; it then speedily distends both lateral ventricles and the third and fourth ventricles, and escapes by the openings at the lower extremity of the fourth ventricle, central and lateral, into the subarachnoid space. Or the blood may escape to the surface, infiltrate the pia mater, and tear its way into the subarachnoid cavity, often by a very small opening. It is rarely that the artery from which the blood has escaped can be detected. Occasionally the extravasation can be traced to the rupture of an aneurism of some size. In other cases military aneurisms may be found on many vessels. The larger arteries commonly present atheromatous changes.

After a time the extravasated blood undergoes changes. The clot shrinks and gradually becomes, first chocolate, then brown, and ultimately a reddish-yellow; and it then contains chiefly fat-globules, pigment and other granules, and hæmatoidin crystals. The rapidity with which it undergoes this change is doubtful, and certainly varies. It is said that the distinctive blood-colour has disappeared as early as the twentieth day. Meanwhile the walls of the cavity undergo changes. The inflammation, in rare cases excessive and purulent, is usually conservative, and leads to the formation of connective tissue. A firm wall is thus developed, the inner surface of which becomes smooth by the softening and removal of the loose fragments of brain-substance; by this means a cyst is formed. It is said that connective tissue may extend across its cavity, and that in rare cases, the fluid being absorbed, the cyst walls may unite, and a cicatrix result. Such cicatrices are, however, much more frequently due to softening than to hæmorrhage. It is asserted that a cyst may be developed in thirty or forty days under favourable conditions.

Hæmorrhage may occur in any part of the brain, but is more frequent in some situations than in others. The most frequent seat is the corpus striatum and the region just outside it: nearly half the intra-cerebral hæmorrhages are in this situation. Other primary seats, in the order of frequency, are the pons and peduncles, the cerebellum, the cortex, the optic thalamus (often affected by an extension of the hæmorrhage from the corpus striatum), the posterior portion, and the anterior portion of the hemisphere. The frequent extravasation into and outside the corpus striatum, is explained by the vascular supply. (*See BRAIN, Vessels of, Diseases of.*)

Traumatic hæmorrhage occurs into and from a lacerated portion of brain, and is most frequently found on the surface, occupying mainly the middle of the convex portion of each convolution, and some other regions much exposed to injury, as the surface of the temporo-sphenoidal lobe, and the under surface of the frontal lobe. Ventricular hæmorrhage sometimes results from traumatic rupture of a small vein on the surface of the corpus striatum (Prescott Hewett).

Soft tumours (especially glioma) are sometimes the seat of hæmorrhage. The distinction from simple hæmorrhage (sometimes difficult) rests on their position being commonly one in which cerebral hæmorrhage is rare; and on some gelatinous-looking tumour-substance being found, into which hæmorrhage has not occurred, and which has characteristic microscopic features.

Other organs may be healthy, or present the changes which have been mentioned as predisposing causes; the lungs are usually secondarily congested, often intensely.

SYMPTOMS.—The occurrence of cerebral hæmorrhage is indicated by cerebral symptoms of two classes, the one general and more or less transient, the other local and more or less permanent. In addition to these there are sometimes premonitory symptoms; and commonly general symptoms manifested by pulse, temperature, &c., which are secondary to the brain-lesion.

Premonitory symptoms, somewhat rare, are those of altered cerebral function due to local vascular disease, headache, vertiginous feelings, local weakness or numbness, slight mental changes, and slight affection of speech (*see BRAIN, Vessels of, Diseases of, and BRAIN, Anæmia of*). They are less frequent than in cases of softening, and more commonly precede cerebral hæmorrhage in the old than in the young and middle-aged.

The onset of hæmorrhage is usually accompanied with apoplexy, i.e. loss of consciousness and of power of motion and of sensation, often with relaxation of the sphincters and loss of reflex action (*see APOPLEXY, Cerebral*). These symptoms are profound and lasting according to the size of the hæmorrhage and its position; being especially marked in large and double effusions, in intraventricular hæmorrhage, and in hæmorrhage into the pons. In a case of moderate severity they last only a few hours, and gradually pass away. In severer cases they may deepen until death occurs from failure of respiratory power. Death is rarely very speedy, life being usually prolonged for some hours even in the most

rapidly fatal cases. In rare instances of hæmorrhage into the medulla, and also in meningeal hæmorrhage, death has occurred in five minutes, probably in each case from the rapid interference with the respiratory centre.

The temperature is at first lowered one or two degrees, the pulse becomes less frequent, and the respiration slow. The Cheyne-Stokes respiratory rhythm often precedes death. After a few hours the temperature rises to the normal and in mild cases stops there, but in graver cases it rises above the normal two or three degrees. In some very grave cases the initial fall or subsequent rise may be extreme and go on until death occurs, sometimes reaching 90° in the one case, and 107° or 108° in the other (Bourneville).

In slight cases of cerebral hæmorrhage there may be no loss of consciousness. Vomiting in such cases is not infrequent. In other rare cases of large hæmorrhage, especially between the external capsule of the corpus striatum and the island of Reil (Broussier), the loss of consciousness comes on gradually, after other symptoms, as of shock, for example, have lasted for an hour or two. These cases have been termed *ingravement*.

Local symptoms, often permanent, and always of longer duration than the loss of consciousness, are present in all cases of circumscribed cerebral hæmorrhage, except in the rare instances in which, by its central position in the pons and medulla, it causes directly bilateral effects only, which are added to and intensify the general symptoms caused indirectly. In a unilateral cerebral lesion, the direct symptoms are unilateral loss of power of voluntary movement and often of sensation, accompanied sometimes with convulsion or rigidity. These local symptoms may commence a few minutes or longer before the loss of consciousness. They coexist with the apoplectic condition, and may often be recognised, even during coma, by the flaccidity of the paralysed limbs, which fall more helplessly than those of the opposite side; by inequality of the mouth and of the pupils; by conjugate deviation of the head and eyes towards the side of the brain injured; by convulsive movements; and, as the apoplexy clears, by the detection of unilateral defect of sensibility. The coma passing away, these signs become more distinct, and all the symptoms of hemiplegia remain, varying in intensity and extent according to the position of the lesion. The apoplectic state may recur after its disappearance—a grave symptom, usually indicating that a fresh hæmorrhage has occurred in the same or the other side of the brain, or more frequently that the blood has seeped into the ventricles. In the former case the unilateral symptoms, conjugate deviation of the head and eyes, &c., are increased on the same, or transferred to the opposite side; in the latter the unilateral symptoms disappear, and general powerlessness and deep coma supervene, with stertor, relaxation of the sphincters, lowered temperature, and impeded respiration. Death always ensues.

Convulsion may be a conspicuous symptom at the onset or subsequently. It is usually unilateral in its course or commencement, beginning on the side paralysed, rarely affecting only the non-paralysed side. Where contractions

not met with, muscular twitching or rigidity may occur. General or widely-spread rigidity or twitching points to a bilateral lesion; if with coma, to ventricular hæmorrhage.

After a day or two symptoms of irritation about the cerebral lesion come on, such as headache, delirium, and rigidity in the paralysed limbs. During this period the temperature rises above the normal, and the pulse becomes quick. On their subsidence, these symptoms, if the lesion is slight, may be scarcely recognisable, and a stationary period ensues, at the end of which recovery of power over the paralysed limbs begins. In slight cases power may be recovered very speedily. Its return depends upon the structural recovery of slightly damaged tissue, and on other parts taking on an increased function in compensation for that which is destroyed. The electric irritability of the muscles exhibits little change. Sometimes, however, when there is great irritation at the lesion propagated downwards to the cord, a marked initial increase in irritability may precede a considerable depression, coincident with rapid wasting. Recovery of power is rarely complete except in those cases in which the area of damage is very small; and when the damage is large and affects an important motor region, there may be no recovery, loss of power persisting, commonly with more or less 'late rigidity' in the paralysed limbs. Slight permanent mental change often remains, and as the motor power is recovered, ataxic and other disorders of movement may supervene in the limbs which were paralysed, although much less commonly than after softening.

DIAGNOSIS.—The diagnosis of cerebral hæmorrhage rests on the symptoms of a localised cerebral lesion, occurring suddenly. The conditions from which it has most commonly to be distinguished are—congestion of the brain; softening of the brain, embolic and thrombotic; and, sometimes, tumour. For the distinction from it of other causes of apoplectic loss of consciousness, uræmia, post-epileptic coma, &c. see **APOPLECTY, CEREBRAL**. From *congestion* the chief distinction of cerebral hæmorrhage lies in the transient nature of the loss of consciousness; and in the slightness and general character of the symptoms which characterise the former. Congestion generally, hæmorrhage only sometimes, comes on during effort: and the absence of history of effort is in favour of the latter. Similarly, the premonitory symptoms which are usually present in congestion, are generally absent in hæmorrhage. The loss of motor power, and the symptoms of cerebral shock, are much greater in hæmorrhage than in congestion. It must be remembered that the two states frequently coexist. From *softening* consequent on *embolism* cerebral hæmorrhage has also to be distinguished. The subjects of the latter are usually of an earlier age than those of hæmorrhage; their vessels are healthy, but they have *chronic* heart-disease, which is often grave. There may be evidence of embolism elsewhere, in spleen, kidney, or retina. Loss of consciousness may be absent in embolism, and the paralysis often comes on deliberately. An extensive *arterial* embolism, causing deep coma, cannot be distinguished from hæmorrhage. From

softening due to *thrombosis* the distinction is often difficult. Age, and the state of the vessels, no longer serve as guides. The presence of chronic Bright's disease is in favour of hæmorrhage. The occurrence of previous hemiplegic attacks points to softening. In the attack, loss of consciousness is much more considerable, in proportion to the subsequent paralysis, in hæmorrhage than in softening. But the distinction on this ground is often very difficult, since loss of consciousness may be absent in slight hæmorrhage, and considerable in an extensive softening. A deliberate onset is in favour of softening, and so are much mental change and 'early rigidity'. Paralysis of sudden onset, in cases of *tumour*, may be ascribed to hæmorrhage, to which it is indeed sometimes, but not always, due. Usually, enquiry elicits a history of gradual, long-continued symptoms; intense headache and optic neuritis are strongly suggestive of tumour.

Hæmorrhage into the substance of the brain is distinguished from *meningeal hæmorrhage* by the pain and mental excitement being less conspicuous, convulsion rarer, and by the presence of symptoms of a local lesion. *Hæmorrhage into the ventricles*, which resembles meningeal hæmorrhage in the generality of its symptoms, is usually distinguished by succeeding the symptoms of a circumscribed lesion.

PROGNOSIS.—During the attack itself the prognosis in hæmorrhage into the brain must be guided by the intensity of the symptoms, and by the place of the lesion, as far as that can be ascertained. Death is probable if the coma is profound or long-continued, and if the early depression, or the subsequent rise of temperature and pulse-rate is great. When the symptoms indicate ventricular hæmorrhage, or hæmorrhage into the pons, the patient will certainly die. Consciousness being recovered, and the danger of immediate death over, the freedom from much secondary pyrexia, from lung-congestion, and from bedsores, are favourable indications. The chance of recovery from the paralysis is estimated by evidence of position of the lesion, and by any indications of improvement. Early contraction of the flexors is unfavourable. The danger of recurrence is in proportion to the extent of vascular disease, and the existence of irremovable causes of increased arterial tension. Hence the prognosis is rendered unfavourable by advanced age, or chronic renal disease, and by the evidence of general premature decay.

TREATMENT.—*During the attack.* Rest is the most important. The patient should remain, as far as possible, where he is seized; stillness must be secured: and all effort is to be avoided. The posture should be recumbent, with the head raised. Any cause of passive cerebral congestion, such as a tight collar, must be looked for and removed. Venesection was formerly almost always employed in such cases—certainly too universally; but it is now quite discarded—perhaps too absolutely. Loss of blood lessens the force of the heart and vascular tension; it thus hastens the cessation of external bleeding. Doubtless it acts in the same way in internal hæmorrhage. It may be used with probable advantage if the arterial tension is great (that is if the pulse is incompressible), the heart acting strongly, and there is

reason to believe that the intra-cranial hæmorrhage is increasing. A small quantity of blood should be taken rapidly. In ventricular hæmorrhage, venesection is probably powerless for good. It should not be employed where there is any evidence of failing heart-power. Its indications are drawn as much from the state of the patient as from the fact of hæmorrhage. Bright's disease is no contra-indication.

If bleeding is not employed, the objects to be aimed at by other measures must be to divert the blood as far as possible from the brain, by relaxing the systemic vessels, while endeavouring to obtain contraction of the cerebral vessels. Warmth may be applied to the limbs, aided by sinapisms. Dry-cupping to the surface, and purgatives, as croton oil, will divert the blood to the surface, or to the capacious intestinal vessels. Drugs which would cause contraction of the vessels are to be avoided, since their influence being on the smallest vessels and universal, their tendency is to increase arterial tension and hæmorrhage. Contraction of encephalic vessels may be furthered by cold to the head or sinapisms to the neck, according as the head is hotter or colder than normal. The heart should be allowed to fall a little below the normal in force, but failure of power must be ward off by stimulants given with great care. Convulsion is more effectually checked by cold than by bromides; the latter may be given if the convulsion recurs.

After the attack.—During the stage of irritation, rest must be maintained, and all sources of annoyance must be avoided. The bowels should be kept gently open by laxatives or by injections. Stimulants must be avoided, and the diet should be light. Pain may be relieved by cold to the head, a blister to the neck, or by Indian hemp or by bromide of potassium.

During reparation the diet must be nutritious, but carefully regulated; and constipation of the bowels must be avoided. Rubbing of the limbs, and their gentle exercise, will aid their recovery, and after the symptoms of irritation have passed, faradisation will improve muscular nutrition, and is especially indicated where rapid loss of irritability indicates probable wasting. Nerve tonics are useful; none more so than a combination of hypophosphite of soda and tincture of nux vomica. In æmia the syrup of the phosphate of iron is good. Warmth, change of scene, and cheerful mental surroundings are useful adjuncts, especially in the later stages of recovery. W. R. GOWMAN.

BRAIN, Hyperæmia of.—**SYNOM.**: Congestion of the brain.

DEFINITION.—Increase in the quantity of blood within the capillaries of the brain.

Since neither the arteries nor the veins of the brain-substance can be over-distended with blood without capillary hyperæmia, and since it is to capillary hyperæmia that the functional disturbance of the brain is related, this may be justly taken as the essential pathological element in cerebral congestion. The congestion may be *active*, when the capillaries contain, in consequence of arterial distension or dilatation, oxygenated blood passing rapidly through them; or it may be *passive*, when, from venous obstruc-

tion, the capillaries contain slowly-moving blood, becoming, and in great part already, venous.

ÆTIOLOGY.—(A) *Active* congestion of the brain may be *general* or *partial*. Of the general form the remote causes are as follows:—Men are said to be more liable to it than women. Age increases its frequency (but this is more true of the passive form); yet children, from the sensitiveness of their vaso-motor system, occasionally suffer from active cerebral congestion. Heredity has only an indirect influence. The plethoric condition is a powerful predisponent. The *immediate* causes of excessive flow through the arteries of the brain may be thus stated:—(1) Increase in the blood-pressure—either general, from excessive action of the heart (as in extreme hypertrophy or functional overaction); or partial, from an obstruction elsewhere, throwing an undue proportion of the pressure upon the cerebral vessels. This is seen in contraction of the aorta beyond the origin of the vessels to the head, and in sudden contraction of a large number of the systemic arterioles, as those of the surface, in exposure to cold and in ague. (2) Active arterial dilatation of vaso-motor origin may result from prolonged mental work, severe moral emotion, insolation, digestive disturbances, or from the presence in the blood of various poisons, such as alcohol and amyl-nitrite. In these cases the vaso-motor disturbance may precede and cause, or may succeed and result from the overaction of the brain-tissue, which is intensified by it. In acute alcoholic poisoning the cerebral congestion is, as Niemeyer suggests, probably secondary to the disturbance of brain-tissue; in chronic alcoholism it may possibly be primary. In pyrexia the headache and delirium have been thought to be due to congestion, but this is not certain. (3) Increased atmospheric pressure may cause congestion of the brain. (4) And, lastly, gravitation in the recumbent posture may alone cause cerebral hyperæmia, or may powerfully aid other causes in producing it.

Partial active congestion of brain-tissue occurs chiefly along with disease of the arteries, which perverts blood-pressure; in organic brain-diseases, as tumour, hæmorrhage, &c.; and after blows on the head.

(B) *Passive* congestion of the brain, when *general*, is the result of impeded return of blood from the head. It may be due to pressure on the veins in the neck, as by tumours or tight collars; pressure on the innominate veins by tumours or aneurism; or obstruction to the circulation from violent respiratory efforts, as cough or blowing wind-instruments. It may be caused by impediments within the circulation, such as tricuspid insufficiency and its causes in the lungs, or disease on the left side of the heart. The recumbent posture assists all these influences. In arterial obstruction from diseased vessels, a weak heart, insufficient to overcome the obstruction, may permit venous stasis, but the capillary condition is one of *æmia*.

Partial passive congestion may occur from thrombosis in a cerebral vein, or from pressure by a growth on one of the cerebral sinuses.

ANATOMICAL APPEARANCES.—The capillaries are not visible to the naked eye even when

distended, but with the microscope they are seen to be dilated, often to twice their normal calibre. Their distension is indicated by a deeper tint of the grey substance; and the fullness of the small arteries and veins shows itself in an increase, often very great, in the number and size of the red points visible on section of the white matter. In active congestion the arteries are said to be distinctly larger than normal, and their perivascular spaces lessened in size; the minute vessels of the meninges are distended. In passive congestion the veins and sinuses are gorged with blood. It must be remembered, however, that such engorgement of the veins occurs in all cases of death from interference with respiration, and that the vessels of the most dependent portion are always fullest. The state of the cerebral veins must therefore be carefully compared with that of the veins of other organs. Active congestion may sometimes leave no visible traces. After a time blood-pigment collects outside the vessels (Bastian), and serous effusion into the pia mater may be found, and after long-continued congestion, the vessels may be permanently distended; the spaces in which they run are increased in size. Such increase is common apart from pathological congestion, but it is so great in some cases of long-continued congestion that this effect cannot (with Moxon) be altogether denied.

SYMPTOMS—It is probable that many symptoms have been erroneously ascribed to cerebral congestion, some because hyperæmia, due to the mode of death, was found *post mortem*, others because an assumed congestion was the readiest mode of explanation. Moxon has indeed maintained that cerebral hyperæmia never causes symptoms except perhaps in death from strangulation. It is doubtful whether our knowledge of the conditions of the cerebral circulation is sufficiently exact to justify this conclusion, which is difficult to reconcile with clinical facts.

The symptoms commonly referred to cerebral congestion may be grouped in two classes—those of excitement, and those of depression. Either of these may exist alone; those of excitement may precede those of depression, or they may partially co-exist. They may be slight or severe; acute or chronic. In all cases they are increased by the recumbent posture or by depressing the head, by expiration, and by effort, and they are usually aggravated by constipation, and by indulgence in alcohol.

In general cerebral hyperæmia, among the symptoms of excitement may be mentioned mental irritability; headache—slight or violent, with feelings of fullness or throbbing in the head, and vertiginous or other unpleasant sensations; increased or perverted functions of the organs of special sense, such as flashes of light and noises in the ears; contraction of the pupils; restlessness, restlessness, startings, twitchings or slight actual convulsions; and mental excitement. The pulse is quick. There may be vomiting. The face varies, participating in the conditions of circulatory origin, and in some of vaso-motor disturbance, such as that which may occur during digestion. In other forms of suppurative congestion of vaso-motor mechanism, as in those which result from excessive brainwork, the

face may be pale, but the nature of these cases is doubtful.

Among symptoms of depressed brain-function are dullness of the special senses; motor weakness, mental indifference and slowness; somnolence, especially after meals; dilatation of the pupils; and infrequency of the heart's action. Consciousness may be lost suddenly, and the loss, it is commonly believed, may deepen into coma. As a rule there is no fever, but in children the temperature may be raised a degree or so.

In the *chronic* forms of cerebral congestion, these symptoms, variously grouped and moderate in degree, continue for days, weeks, or months. Their course is marked by great variability. Durand-Fardel has pointed out that in these cases there is often much viscid secretion of the conjunctiva.

In the more *acute* forms of cerebral congestion, the symptoms of muscular spasm, of mental disturbance, or of loss of consciousness, may be so predominant as to give a special character to the attack:—

In the *convulsive* form pain or uneasiness in the head commonly precedes the muscular spasm. The latter is usually slight. Consciousness may or may not be lost.

The *delirious* form is seen under two aspects—(1) in old age, after emotional excitement; in this the wandering is slight, and often related distinctly to the recumbent posture; (2) a much more violent delirium, which is apparently related to cerebral congestion, and is seen sometimes after mental work or emotional excitement, or after alcoholic poisoning. Occasionally death results.

The *apoplectic* form is marked by sudden loss of consciousness, occurring commonly during effort. The unconsciousness usually lasts only a few minutes, and incomplete general weakness remains for a day or two. In rare cases the loss of consciousness deepens into coma, with stertorous breathing and relaxed sphincters, and death may occur from the extension of the cerebral depression to the respiratory centres. *Vertiginous* sensations sometimes give a character to an attack.

In children congestion of the brain is a rare but occasional cause of convulsion or delirium. Headache and contracted pupils make up a group of symptoms resembling meningitis, but fever is rarely present, and if it exists it is slight, and the symptoms usually come on suddenly and pass away in a day or two.

Partial hyperæmia leads to localised symptoms of excitement or depression. Local convulsion or paralysis may result. Headache is often intense and localised. If nothing more than congestion is present, the symptoms usually soon pass off.

PATHOLOGY.—The pathology of cerebral congestion is still obscure, since we know little of the relative part played by the blood-vessels and the nerve-elements in determining the symptoms and their form. An excessive supply of arterial blood is, in all organs, attended with functional activity, and it is easy to understand that active congestion should result in symptoms of excitement. Subsequent depression of function has been accounted for by inferring compression of brain-tissue by effused

serum. The reaction of exhaustion may contribute. In passive congestion the nerve-tissue is imperfectly supplied with oxygenated blood, and compressed by distended vessels, and its functions are impaired by the presence of effete products. Hence the predominance of symptoms of depression over those of irritation.

DIAGNOSIS.—The diagnosis rests on the discovery of circulatory and other causes of cerebral congestion; on the circumstances of posture, effort, &c., under which the symptoms came on; on the existence of concomitant congestion in other parts supplied by the carotids, as the face (by no means invariable); on the diffusion of the symptoms; on their speedy disappearance; and on the absence, in the adult at any rate, of elevation of temperature. The diagnosis of the special forms of cerebral congestion from the diseases which they most resemble is considered under the head of those diseases.

PROGNOSIS.—The prognosis is generally immediately favourable, but from a severe attack death may probably occur. The apoplectic form is most dangerous, the convulsive least so. Degenerated weakened vessels render the immediate prognosis less favourable. After many attacks, permanent nutritive changes in the brain supervene.

TREATMENT.—The most important elements in the treatment of cerebral congestion are posture, removal of blood, purgation, cold to the head, and warm and stimulating applications to the surface. Whatever be the cause, it is important to raise the patient's head, so that gravitation may impede the flow and aid the return of the blood. By this means alone insomnia from hyperæmia may often be prevented. The removal of blood is useful in extreme forms of congestion, either active or passive, especially in those forms of active congestion in which the face participates. Venesection or leeching may be employed according to the severity of the attack; in active congestion the blood which is taken should be removed quickly. The relief which in such cases follows an epistaxis illustrates the value of this method of treatment. It is not advisable in those cases in which, from overaction of brain-tissue, or from cold to the surface, dilatation of the cerebral vessels results, while the face remains pale. In all forms of congestion, purgation is useful. It removes from the blood some of its serum, and it affords immediate relief to the cerebral circulation, by causing an afflux of blood to the capacious intestinal vessels. In plethoric states diuresis is also most useful, and has succeeded where venesection and purgation failed (Reynolds). Cold to the head is of most value in reflex or secondary dilatation of the cerebral vessels, as after mental work, insolation, fatigue, and some toxicæmic states. In the same class of cases, stimulation of the peripheral nerves by sinapisms, blisters, &c., applied to the neck, will, by reflex influence, assist in obtaining arterial contraction. Hot applications to the limbs act in part in a similar manner, in part by causing local afflux of blood and thus lessening the tendency to encephalic engorgement. They are most useful in active congestion. Alcohol and opium must be avoided in all forms of active congestion, but

in passive congestion they may be of service. Bromide of potassium is useful in those cases in which the congestion is produced by vasomotor mechanism, excited either by stimulation of brain-tissue or of distant nerves. In passive congestion from heart-disease the treatment is that of the cardiac condition. All persons liable to congestion of the brain should live regularly, avoid hot rooms, and attend carefully to the stomach and bowels, relieving the latter by frequent moderate purgation.

W. R. GOWERS.

BRAIN, Hypertrophy of.—Hypertrophy of brain is a misnomer. True hypertrophy would consist of increase in number or in size of the nerve-cells, nerve-tubes, connective stroma, and supplying vessels: and there might be expected, as a result of this condition, some manifestation of a higher intellectual development. Such a condition is never found. A so-called hypertrophied brain is one that is larger and heavier than normal. On removing the skull-cap, the encephalon seems to expand, so as to render it difficult to affix the bone-covering in its place; the membranes are dry, the sulci have nearly disappeared, and the whole organ appears pale and bloodless. On section there is a sensation of toughness, though less in degree than in a case of general sclerosis. There is no sign of pressure upon the orbital plates, such as is met with in chronic hydrocephalus. The lesion affects only the cerebral hemispheres, especially on the convex surface, and perhaps the posterior lobes in particular. The base of the brain and the cerebellum are unaffected except by pressure.

On minute examination, the nerve-cells and nerve-fibres, far from being found augmented in number or in size, may even be compressed and diminished; and there is often also some interference with the normal calibre of the vessels. Gintrac, however, records a case in which the calibre of the nerve-tubes was almost double that of the normal. What increase there is affects the white matter of the brain, and this structure is very pale and of an elastic consistence. The real and sole lesion is hyperplasia of the connective tissue. It differs from sclerosis in affecting the cerebral hemispheres more universally than is the case with sclerosis, and also that in sclerosis there is not only increase of the connective tissue, but subsequent retraction, and, as a frequent consequence of this, an absolute destruction more or less of the nerve-elements of the organ. When the disease is far advanced it may possibly cause absorption of the inner table of the skull, and thus produce a roughness or thinning of the bone, or, in extreme cases, even perforation. The sinuses are generally distended with blood. Hypertrophy of smaller portions of the brain is rare: still various cases are on record in which, under the name of *neurorhiza* of the nervous centres, white or grey matter has been found in certain parts of the brain over and above the normal constituents of this organ. Hyperplasia of the pineal gland is closely allied to glioma. It should be distinguished from encysted disease of that organ.

Ætiology.—Hypertrophy of the brain has been

and to be sometimes secondary, and caused by the irritation of morbid growths. This, however, is rare. It is generally primary, and may be a disease of intra-uterine life; but it is generally developed after birth, especially in rickety children. Some forms of encephalocele, without hydrocephalus, seem to be due to the growth of compact masses of cerebral substance in excess of what is normal. The conditions for the production of this morbid state are infancy; bad diet, repeated congestion of the cerebral vessels, such as might be induced by frequent cough; and, perhaps, lead-poisoning.

SYMPTOMS.—The symptoms of so-called general hypertrophy vary according as the sutures are closed or not. If, from insufficient occlusion of the sutures, the head expands in proportion to the increase in size of the encephalon, the symptoms may be very slight. Children thus affected show no intellectual hebetude. In them, as long as the abnormality is uncomplicated with local inflammation of membranes or with hemorrhages, there may be no headache, no affection of sight, no sensory or motor paralysis, and no convulsions. Convulsions, however, are common in cases in which the occlusion of the sutures has prevented expansion of the head proportionate to the internal increase of tissue. In such cases also there is generally more or less motor paralysis, often some anesthesia of the limbs, headache, vomiting, and mental hebetude—symptoms, in fact, either of marked interference with the intra-cranial circulation, or of irritation from inflammatory complications. The prognosis is always bad, but in rachitic cases the course may be chronic.

TREATMENT.—All treatment seems to be ineffective in diminishing cerebral hypertrophy.

E LONG FOX.

BRAIN, Inflammation of.—**SYNON.**: Encephalitis.—Encephalitis is a term which ought perhaps to be strictly limited to inflammatory changes in the brain-substance itself, to the exclusion of all forms of meningitis. It may be either *diffuse* or *local*, but for our present purpose we have chiefly to do with the diffuse form. Local encephalitis will generally result in abscess (see **BRAIN, Abscess of**) and will usually be met with, if we put aside the results of injuries, in association either with disease of the ear, with tubercular growths, or with pyæmic deposits.

It may perhaps be doubted whether the occurrence of diffuse inflammation of the brain-substance as an acute disease has as yet been proved, excepting as a result of wounds. Even as a traumatic lesion, its special features have by no means been accurately studied. It is, however, highly probable that after penetrating wounds of the brain, its substance may inflame, just as the cellular tissue of a limb may, the inflammatory processes beginning at the site of the wound and rapidly spreading through a large part of the hemisphere. It is probably in the perivascular spaces that the process chiefly spreads, and it is in these that the microscope will detect the most abundant results. Such a condition of diffuse encephalitis may exist without there being any visible changes in the brain. It may perhaps be a little softened or a little

congested, but very probably there is nothing about which the most experienced pathologist could feel certain until the microscope is resorted to.

SYMPTOMS.—It is not possible, in the present state of our knowledge, to speak with any certainty of the symptoms of diffuse encephalitis. They will vary, of course, with the region affected, and disturbance of function, followed by more or less complete loss, will be the most frequent occurrence.

TREATMENT.—When the symptoms of encephalitis are once recognised, it will usually be too late for treatment, and measures of prevention are those of chief importance. The early use of mercury, beginning in anticipation of rather than waiting for symptoms, is probably the most important; and next to it come cold to the head, purgatives, and counter-irritation.

JONATHAN HUTCHINSON.

BRAIN, Laceration of.—In the most strict sense of the word, the brain is but little liable to laceration from injury. Yet, in connection with injuries, such as penetrating wounds of the skull, fractures with great depression of bone, and even with violent concussions, the brain-substance is not unfrequently, to some extent, torn. In so soft a structure, however, and under the influence of modes of violence which are usually rather of the nature of blows than of anything likely to cause stretching, we rarely meet with results comparable to laceration of any of the firmer textures of the body. Whenever the brain is 'lacerated' it is also contused, and the confusion often extends widely around the rent, and is by far the more important lesion. In the peripheral parts of the brain-mass this is especially true, and it is of little practical use to speak of lacerations excepting as complications of very severe contusions. In the central parts, the crura especially, we meet now and then with a laceration properly so called, and it is not very infrequent to find the trunks of single nerves torn across. The consideration of those forms of laceration which are produced by the effusion of blood from ruptured vessels of size sufficient to supply a stream forcible enough to break up the surrounding substance, will be found in the articles **APoplexy, CEREBRAL**; and **BRAIN, Hemorrhage into**.

In the case of injuries to the head from falls or blows without perforation, certain definite parts are prone to suffer from contusion and laceration. Usually some slight evidence of injury is found immediately beneath the part of the skull upon which the blow was received, but by far the chief bruising will be at the opposite point. If the occiput be struck, the anterior lobes will be contused; and if one parietal eminence, the opposite sphenoidal lobe. This law, however, is greatly modified by the differing conditions under which different parts of the brain-mass are placed as regards their surroundings. In the posterior half of the skull the brain-mass is bulky, and between its hinder lobes and the cerebellum is a strong flexible membrane, well calculated to break vibrations gradually, and thus to prevent contusion. Nor are there in these regions

any strongly marked bony ridges against which the brain might be dashed. These conditions are reversed as regards the anterior lobes and the middle lobes, and the consequence is that whilst severe contusions are often seen in the latter, they are much more rare in the cerebellum and posterior two-thirds of the brain-mass. In cases of compound fracture, with tearing of the dura mater, and deep depression of bone, the brain-substance may, of course, be injured at any part; but even in respect to this kind of violence the hinder regions of the skull are specially protected.

SYMPTOMS.—We know enough of surface-lacerations of the brain in parts other than the anterior and middle lobes, to be able to assert that, unless the lesion extend very widely or deeply, it does not reveal itself by any special symptoms. If very extensive, weakness of the opposite limbs and side of the face is usually observed. Injury to the anterior lobes, unless extensive, cannot be diagnosed, but it may be guessed at in a few cases where the sense of smell is lost in one or both nostrils; for it is very common for the olfactory bulbs to be damaged at the same time. If the anterior lobes are severely lacerated, the symptoms will be those of very severe concussion, with the difference that the insensibility is more nearly complete, and that it increases instead of diminishing as the days pass on. When a sphenoidal lobe is contused there is usually, according to the writer's observation, incomplete hemiplegia of the opposite side, involving sensation as well as motion, and the face as well as the limbs. From these symptoms the patient may, in the course of months, wholly recover. It is usually the apex of the sphenoidal lobe which is lacerated, but if the lesion extends higher, and if it occur on the left side, aphasia may be present.

In connexion with recent discoveries (Dr. Hughlings Jackson, Dr. Ferrier, and others) as to localised functions, no doubt we shall be able before long to diagnose more accurately as to the precise regions injured. It would, however, as yet be premature to attempt to do so.

TREATMENT, and PROGNOSIS.—In the treatment and prognosis of lacerations and contusions of the surface of the brain, much depends upon whether or not the case is complicated by compound fracture and the admission of air. If air have been admitted there is risk of meningitis or encephalitis, denoted in either case by the occurrence, within a few days of the injury, of hemiplegia of the opposite side. To prevent this must be the object of treatment. The scalp should be shaved, the wound closed with sutures as far as practicable, and but wetted in a spirit-and-lead lotion should be laid over the part and systematically re-wetted every hour. If the case be treated in hospital it may be well, in addition to this, to wash the wound with the lotion before closing it, or to dress with Lister's antiseptic precautions. In cases of laceration without access of air death may ensue from diffuse softening around the part. If this happens the case will probably end within a week or ten days. It is probable that many cases of fractured base with more or less severe laceration of brain recover; in some with permanent paralysis, but in others without. It must be added that many of the cases

in which death occurs within a few hours or a day or two after fracture of the base are attended by laceration. In these the symptoms are often difficult to distinguish from those of compression. Profound insensibility, a bloated face, stertorous breathing, and a full pulse, are often present, but they may be substituted by pallor and a feeble pulse in connection with great depression of the heart's action. If any deviation from symmetry as regards the paralysis of the limbs can be proved, it is in favour of laceration and against compression, but the differential diagnosis is a matter of extreme difficulty.

Laceration of Cranial Nerves.—Lacerations of single nerves within the cranial cavity are not by any means uncommon. This occurrence is to be suspected whenever the parts supplied by a cranial nerve are completely paralysed, without accompanying symptoms indicative of severe lesion of the brain-mass. Cases of laceration of the brain itself may be complicated by laceration of nerve-trunks, and thus the symptoms may become difficult to interpret with confidence.

Of single cranial nerves the olfactory bulbs are the most liable to suffer from contusion; and the third, fourth, and sixth nerve-trunks are those most frequently torn through.

JONATHAN HUTCHINSON.

BRAIN, Malformations of.—The malformations of the cranium and its contents may be divided into two series:—A. Those which are scarcely compatible with life; and B. Those in which life is possible, although the intellectual power may be more or less modified from a healthy condition.

A. The first series will include at least seven forms, in all of which life is so rare that it is impossible to speak of more than the pathological anatomy.

1. *Dierphalia*—in which two heads are found upon a single body, or upon two bodies pretty extensively connected. In the first variety, one head may be attached to the vault of the palate of the other, or may be united to the convexity of the skull. In the second variety the heads may sometimes spring from a single neck. This dicephalous condition is frequently accompanied by malformation affecting the spinal column and spinal nerves, as well as by some incompleteness in the development of the brain.

2. *Monocephalia*—the union of two heads into one, on two separate bodies. The two cranial cavities are united into one. Dissection of the dura mater points to this membrane having been formed out of two, and in like manner the cranial contents are either double, or appear to be single from the union of double organs.

3. *Acephalia*—the complete absence of head. An acephalous monster is usually a twin; and when this is not the case, it is associated with the morbid condition of the uterus of the mother known by the name of uterine hydatids.

4. *Paracephalia*—the head not entirely wanting, but deprived of most of the cranium and of the face. A monster of this kind is generally a twin.

5. *Anencephalia*.—The absolute meaning of this term would be the absence of all cranial contents, but it is made to include certain cases

tion, differing according to the amount of the encephalon developed. The aspect of the head, resembling that of a frog, the considerable projection of the eyes, the flattening of the forehead, and the absence of the cranial vault, are the chief characteristics of this abnormality.

In the first degree, there is absence of cerebrum, cerebellum, mesocephale, and spinal cord. In cases of this kind the cranial vault is generally absent, and the bones at the base of the skull convex and thickened.

In the second degree, the cerebrum, cerebellum, and mesocephale are absent, but a portion of the spinal cord is found. This portion of cord is most usually the lower part.

In the third degree, the spinal cord is pretty complete, but there is still an absence of the cerebrum, cerebellum, and mesocephale.

A few cases have been recorded of the fourth degree, in which no cerebrum or cerebellum are found, but a normal spinal cord, and a pretty complete mesocephale.

In the fifth degree, the cerebrum alone is entirely or almost entirely absent, whilst the rest of the nervous centres are present, though not always in a perfectly complete condition. The seat of the absent cerebrum is often filled by fluid.

Lastly, one case has been recorded in which the cerebrum was present, whilst the cerebellum, mesocephale, and spinal cord were wanting.

Anencephalia, like the other previously mentioned malformations, is due to arrest of development, such arrest depending either on physical injuries to the uterus at a very early period of pregnancy, or to some mental shock experienced by the mother during the first two months after conception. It differs from acephalia, not only by the partial formation of the head, but by the presence of the heart, and other thoracic organs. The ganglia of the sympathetic are usually well-developed.

6. *Pseudencephalia*. In this malformation there is anencephalia *plus* a very considerable thickening of the meninges, which take the place and often imitate the aspect of the brain. Its varieties exactly correspond to those of anencephalia. The tumour formed by the development of the membranes is of variable size and position. It may be frontal, fronto-parietal, or occipital. The real seat of the lesion is the pia mater. The abnormality consists in extreme hypertrophy of this structure, with complete arrest in the development of the encephalon, or of some portion of it. Several observers have recognised certain vesicles in the interior of the membranous tumour, and these have been supposed to be cerebral cells in process of development. It is more in accordance with observation to believe with Gintre that they are connected with the development of the choroid plexus.

7. *Cyclocephalia*. In this monstrosity there is an approximation or actual fusion of two eyes in a common orbit. It is connected with certain abnormalities in the brain, that militate against viability, or at least prolongation of life. The brain itself is generally more or less deficient, especially in its anterior and central portions, and in some cases the nose and mouth are very ill-developed.

8. The second series of cases owe their ab-

normal conditions to injury arising in the course of fetal life; and some forms at least may be due to lesion occurring at a later period than in the first series.

8. *Atelencephalia*—incompleteness of brain or of membranes—is the chief of these forms. This incompleteness manifests itself in seven varieties, according to the part of the encephalon injured by the lesion.

In the first variety, the dura mater is somewhat deficient, being altogether absent in certain situations at the base of the brain. The falx cerebri may be wanting, or from incomplete development it may seem perforated with holes; or the tentorium cerebelli may be absent. There are no symptoms which allow a positive diagnosis of any of these lesions during life.

In the second variety, there is general incompleteness of the brain, or imperfection of several portions of it at one and the same time. Whilst the cranial vault is thrown back, and the lower jaw is short, the base of the skull is large, the cerebral convolutions almost absent, and the cerebellum large. The head is almost always small, and it may present various irregular forms. This coincides with certain internal lesions, partial or general atrophy with consequent serous effusion under the membranes, inflammatory conditions, or thickening of the cranial bones and of the meninges. The incompleteness of the brain varies exceedingly, from a condition in which the whole brain is atrophied, to spots of deficiency, such as the absence of a single convolution, of the septum, or of the pineal gland. The symptoms will necessarily vary much according to the amount of cerebral incompleteness. Where this is general, affecting in some degree all the convolutions, the intellectual powers, as in the microcephalous Aztecs, will be very slightly developed, and their language of the very simplest form. With the brain still more imperfect, there is generally complete idiocy or a condition closely allied to it. The special senses are dulled, particularly sight and hearing. Speech is in abeyance, or is limited to monosyllables. There are various motor phenomena, such as muscular debility, hemiplegia, paraplegia, contraction, convulsion, loss of power over sphincters, dysphagia, vomiting, or feebleness of respiration.

The third variety includes incompleteness of the central parts of the brain. The corpus callosum, the septum, the fornix, the corpora striata, and the cornua ammonis may be imperfectly developed. The cerebral hemispheres may thus be in some sort fused together, and the shape of the ventricles altered. The symptoms differ from those of the preceding variety, in that the special senses are seldom involved; and that, although complete idiocy may accompany these lesions, it is more usual for the brain to be found capable of some slight intelligence, though unequal to the conception of abstract ideas.

In the fourth variety, the lateral portions of the brain are incomplete. This lesion generally occupies one side of the brain, leaving the other hemisphere intact. Several points in the hemisphere may be affected, or the whole of a single lobe. Most usually there is a depression occupying the seat of one or more convulsions. Such

a lesion occasionally attacks the whole hemisphere, giving it the appearance of a large pouch filled with fluid. Sometimes also the neighbouring ventricle communicates with it; or there may be much ventricular effusion, with imperfect development of the corpus striatum, the optic thalamus, the cornua ammonis, the mamillary tubercle, the crus cerebri, and the optic and olfactory nerves of one side. In a considerable proportion of patients so affected, the lesion is accompanied by idiocy, and possibly the inability to speak is connected with this mental condition. Some few patients, however, possessed with some intelligence, have yet been unable to speak; this has been the case even when the lesion has existed on the right side. Deafness is rare; feebleness of sight, various forms of strabismus, and nystagmus common. Very frequently there is hemiplegia of the side opposite to the lesion, and certain other affections of the limbs,—emaciation, incomplete development, contraction, various deformities of the hands, &c. Sensation even in the paralysed limbs is normal; convulsions are not uncommon.

In the fifth variety, there is incompleteness of the anterior portion of the brain. Here both the anterior lobes are affected together. This condition may be associated with some deficiency of the corpus callosum, fornix, and corpora striata. Idiocy is not uncommon, mutism is the rule, but in some patients not idiotic a few words have been possible. Other phenomena—amaurosis, strabismus, and various motor abnormalities—have occurred so irregularly in these patients that it is probable they were symptoms not so much of this lesion as of certain further complications.

Incompleteness of the cerebellum forms the sixth variety. This is sometimes associated with a similar condition of one side of the brain. Usually one lateral lobe only is affected. General hydrocephalus is an occasional complication, and a collection of fluid under the tentorium cerebelli is very common. The symptoms are very negative. In general terms it may be said that there is no loss of muscular co-ordination, and no loss of sexual power.

In the seventh variety, there is incompleteness of the mesocephale and medulla oblongata. This is not carried very far. Certain modifications in form and volume are alone compatible with the preservation of life. It is not a common lesion, and has generally been associated with idiocy.

9. *Congenital hydrocephalus.* One variety of this congenital effusion of fluid is rare, viz., when the fluid is outside the dura mater, between this membrane and the pericranium, and the cranial bones are found floating in the midst of the fluid.

The second variety is that in which the fluid lies outside the brain. The writer believes that serous effusion in this position is not the cause of the atrophy, flattening, or induration of the subjacent cerebral organs, but the effect; that where fluid is found in this situation it is only the consequence of some one of the lesions already mentioned, notably atrophy of brain from whatever cause, and of atelencephalia. This view is, however, opposed to that of some authors.

The third variety is congenital hydrocephalus of the ventricles. In some such cases the increase in the size of the head occurs before birth; in others, not until after. The head increases rapidly in size in the first four weeks after birth. The sutures are widely separated, the cranial bones very thin, the integuments of the head injected, and the hair deficient. The muscles are badly developed, locomotion is imperfect, the intellect is generally obtuse, but the special senses are not particularly affected, unless it be that sight is deficient.

10. *Synencephalia* is merely a matter of pathological interest. The head of the fetus is sometimes found adherent to the membranes or to the placenta, as a consequence of intra-uterine inflammation. At the point of adhesion the place of the cranial bone is taken by a thin vascular membrane. This condition is sometimes accompanied by, and indeed perhaps causes, encephalocoele.

11. *Exencephalia.*—Here a large portion of the brain is situated outside the cavity of the cranium. Practically it includes all the other malformations of the brain that are yet to be spoken of. Thus, if only a limited portion of the brain finds its way outside the skull by an abnormal opening, the displacement is known by the name of *encephalocoele*, or *hernia cerebri*; if this hernia coincide with a hydrocephalic condition of the ventricles, it is called *hydroencephalocoele*; and if the hernia is composed not of the brain, but of the membranes, distended with fluid it may be, the lesion is called *meningocele* or *hydromeningocele*. Exencephalia proper may be subdivided into *frontal*, *sincipital*, and *occipital*, according to the direction taken by the extruded brain.

In encephalocoele only a portion of the brain more or less limited is found outside the skull. The exit takes place most frequently at the occipital, and next in the frontal region; but the temporal and parietal regions are occasionally the seat of this lesion. The symptoms may be very negative. Encephalocoele unless pressed upon externally is not often attended by convulsion or paralysis, by intellectual feebleness, or by difficulty of speech. This latter symptom is sometimes found when the hernia includes the cerebellum. Neither is this lesion incompatible with the prolongation of life. The chief diagnostic difficulty is the possibility of the tumour being cephalæmatoma, but this is frequently situated over the parietal bones, an unusual position for encephalocoele; and external pressure of the former tumour causes none of the cerebral phenomena—stupor, dilatation of pupils, paralysis, convulsion, so constantly seen from compression of an encephalocoele.

BRAIN, Membranes or Meninges of.—See MENINGES, Diseases of.

BRAIN, Morbid Growths of. See BRAIN, Tumours and New Growths of.

BRAIN, OEDEMA of.—DEFINITION.—Infiltration of the brain and pia mater with serum.

ÆTIOLOGY AND PATHOLOGY.—In chronic cases, as in Bright's disease, fluid is effused around the

brain, into the meshes of the pia mater and between the convolutions. Occasionally the cerebral substance is infiltrated, but this is uncommon. The perivascular canals afford a ready means of escape for effused serum, and in Bright's disease, at least, the substance of the brain often contrasts, by its firmness, with the condition of other organs. In senile atrophy of the brain the space between the shrunken convolutions is occupied by serum, and the ventricles contain an excess of fluid. The brain-tissue may appear to contain more fluid than usual in consequence of the distension by serum of the enlarged perivascular canals. In hyperemia, especially passive, such as occurs in heart-disease, serum is commonly effused from the engorged vessels. Such effusion is also common in insanity, especially in acute dementia. The serum may infiltrate the pia mater, distend the perivascular canals, and even infiltrate the brain-tissue.

The effusion of fluid in these cases is usually slight. Occasionally it is more considerable, and the cerebral substance may be enlarged, the convolutions being flattened, and the tissue much lessened in consistence. The same softening is seen in the neighbourhood of effusions of fluid into the ventricles; the brain-tissue for a depth of some lines from the ependyma being softened to a pulpy consistence. The post-mortem imbibition always increases the apparent amount of the oedema.

SYMPTOMS.—Little is known of the symptoms of oedema of the brain. The oedema is usually secondary to some other condition, the symptoms of which mask those of the oedema. General oedema seems attended by slow diminution of mental power and motor force. The effusion of serum in cases of congestion, and consequent pressure on the nerve-elements, has been considered as the cause of the symptoms of depression common in that condition. Cases occasionally occur in which effusion of serum into the ventricles and the pia mater is the only post-mortem condition to be found after an apoplectic seizure, and such cases are often spoken of as instances of *nerous apoplexy*. In so far as the effusion of serum is related to the apoplectic attack, it is probably merely as the consequence of a cerebral congestion which has left no recognisable post-mortem hyperemia.

TREATMENT.—The treatment of cerebral oedema is usually secondary to the condition, commonly conspicuous enough, which is its cause,—Bright's disease, passive cerebral congestion, &c. If oedema be suspected where no causal indication for treatment exists, purgatives and diuretics, with iron if there be debility, are the remedies most likely to be of service.

The effusion of fluid into the ventricles is described under HYDROCEPHALUS.

BRAIN, Sclerosis of. See SPINAL CORD, Diseases of.

BRAIN, Softening of.—**DEFINITION.**—A pathological state of brain-tissue, depending commonly on vascular obstruction; attended by diminished consistence, usually local; and indicated during life by mental, motor, and sensory

symptoms, which vary according to the seat of the lesion.

ÆTIOLOGY.—Local softening of the brain, occurring during life, is due to one of two causes, inflammation or vascular obstruction. Most cases were formerly thought to be due to inflammation; but it is now known that very few are. The vascular obstruction, which is the usual cause of softening, may be arterial or, rarely, capillary; it may be due to a coagulum formed *in situ* (thrombosis), or to a plug of fibrin conveyed into the vessels by the blood (embolism). The predisposing and exciting causes of these conditions will therefore be those of softening of the brain (see BRAIN, Vessels of, Diseases of). The chief concomitant conditions are—in thrombosis, vascular degeneration; in embolism, valvular disease of the heart; and as predisposing conditions we usually find, in cases of thrombosis, advanced age, Bright's disease, chronic alcoholism, or syphilis; in cases of embolism, acute rheumatism, chorea, or scarlet fever. Senile vascular degeneration is the most common cause of all of softening of the brain, and hence the disease is met with most frequently in the old, especially in its recurrent and chronic form. Embolism, due to valvular disease of the heart, and thrombosis due to syphilitic disease, are the most frequent causes of acute local softening in the young and middle-aged.

ANATOMICAL CHARACTERIS.—The characteristic feature of cerebral softening is diminished consistence. This may, however, arise from ante-mortem or post-mortem changes. In each case the diminished consistence depends on the breaking-up of the myelin, of which the nerve-fibres are composed, into globules and granules, and the separation of these by an increased quantity of fluid. Thus the continuous structures of which the brain consists are broken up into disconnected fragments, and the consistence of the tissue is accordingly diminished. In *post-mortem* softening there is nothing more. The globules of myelin are often large, and the separating fluid abundant. The softened tissue has the tint of the normal cerebral substance. The process is the result of the imbibition of fluid from some collection of serum, in the ventricles or elsewhere, and occurs in the greater degree in the immediate vicinity of this. In *ante-mortem* softening there are, in addition, certain changes in the tissue-elements. The process of segmentation of myelin results in the formation of finer granules. These are in part aggregated into 'granule corpuscles' round or oval masses of globules and granules, sometimes contained within a distinct cell-wall. Some of these bodies may arise by simple aggregation, many certainly by the degeneration and distension of connective-tissue cells, and some by the degeneration of nerve cells. The walls of vessels in the softened area also present fatty degeneration. The specific gravity of the tissue is diminished (Bastian). No further change may exist, and the area affected may present simply a diminution of consistence, its colour remaining unchanged. It is then called *white* or *grey softening*. Very frequently, however, in the part thus diseased, distension of capillaries with

blood occurs, most considerable in the periphery, and blood is actually effused, chiefly by rupture of capillaries, in part perhaps by migration of corpuscles. In proportion to the amount of blood extravasated, the colour is changed, and thus *red softening* is produced. After a time, the effused blood degenerates, its tint becomes altered to yellow or orange, and *yellow softening* is produced. Ultimately, it is said, the colour, if at first moderate, may be removed, and white softening result.

Red softening is found chiefly in the grey substance, where the vessels are numerous, especially in the cortex and central ganglia. The tint varies; the red colour is usually punctiform, or mingled with yellow and white. If the extravasations are large and numerous, 'capillary apoplexy' results. The diminution of consistence is usually moderate. According to the amount of effusion of serum and blood there is swelling, and the diseased area may project above the cut surface. Inflammatory changes result from the vascular distension, and in proportion to these, increase in the nuclei of the neuroglia is found. From this cause and from the migration of white corpuscles, pus-like cells appear. The vessels are dilated, and may present a moniliform appearance. Their perivascular sheaths are often distended with blood. Commencing degeneration of the effused blood may cause a brown tint.

Yellow softening results from red softening, by degenerative changes in the blood effused. It has a similar seat, being frequently met with in the convolutions, where it constitutes *plaques jaunes* of the French. Its consistence is usually slight, its aspect granular. The colour depends on the presence of minute pigment granules, diffused colouring matter, and hæmatoidin crystals.

White softening has the tint of the normal cerebral substance. In consistence it varies; it may be only a little below that of the cerebral substance, or it may be diffident. Its aspect is uniform, or white flakes are scattered through it. The limits are usually gradual. Under the microscope it presents the detritus of nerve-elements, a few nuclei from the connective tissue, granule-corpuscles, and, ultimately, corpora amyloidea. White softening is chiefly found in the white substance of the hemispheres. It occasionally has a gangrenous odour, and then may be found in the white or in the grey substance, probably resulting from the obstruction of capillaries by septic material.

Ultimate changes.—White and yellow softening may remain for years unchanged. Sometimes the changes in the elements of the neuroglia and the extravasated white corpuscles result in the formation of a considerable quantity of connective tissue, consisting of fine fibre-cells and fibres, most abundant in the margins of the softened area, which become firm and dense, while trabeculae of connective tissue cross the cavity. After a time the fluid may be absorbed, the fat removed, and a sort of cicatrix result. In other cases the walls alone are thus altered, the solid particles are removed from the softened tissue, and a cyst is formed. The outer portion of the cyst or cicatrix may be limited by a zone of dilated blood-vessels.

Seats of softening.—There is no part of the brain in which softening has not been found, but its most frequent seats are the cortex, the corpus striatum, and the optic thalamus. In the cerebellum, pons Varolii, and medulla it is also frequently found. Its occurrence, position, and characters depend on the distribution of the vessels. The small arteries of the corpus striatum and optic thalamus are 'terminal arteries,' having only capillary communication with other vessels. The arteries to the surface of the brain are usually for the most part terminal, but sometimes possess arteriole-anastomoses with other branches. Hence obstruction in the central arteries leads invariably to softening. Obstruction in the superficial arteries also usually causes softening, which involves the grey substance of the convolutions and some of the subjacent white centre to which the vessels penetrate; but occasionally the anastomoses of the superficial vessels are so free that softening does not result. An obstruction of a main trunk (as the middle cerebral) may lead to softening of the central region (corpus striatum), while the convolutions escape; but usually both suffer.

SYMPTOMS.—The *premonitory* symptoms of softening depend upon its cause. In embolism other symptoms than those of the cardiac trouble are usually absent. Occasionally a slight attack of loss of cerebral function, due to a slight embolism, may precede a graver attack. In softening due to arterial disease, premonitory symptoms of local cerebral anæmia are frequently present. There is defective nutrition of many parts of the brain, revealing itself by symptoms of wide range—mental deterioration; numbness, pains in the limbs, pain in the head, or slight local weakness. These symptoms are of especial significance when associated with evidence of arterial degeneration elsewhere; with the conditions—as chronic Bright's disease, alcoholism, and senility—in which atheroma of the cerebral arteries is common; or with constitutional syphilis.

The symptoms of *actual* softening are those of loss of function in the damaged portion of the brain. The onset of the symptoms may be sudden, as in embolism, and sometimes in thrombosis; or it may be gradual, as occasionally in thrombosis. In the former case the symptoms of initial shock are added to those proper to the locality. The latter are fully considered in the articles on Localisation. Hemiplegic symptoms and mental alteration are the most common. Hemiplegia especially occurs in embolism, on account of the frequency with which the middle cerebral artery is obstructed, and of the important motor regions (corpus striatum and motor parts of the convolutions) to which that artery is distributed. From the distribution of the artery to the lower frontal convolutions and adjacent region, aphasia is frequently present when the obstruction is on the left side.

When the symptoms come on suddenly, they often follow some exertion, or occur during exhaustion. If the area damaged be extensive, there is loss of consciousness, and there may be all the symptoms of an apoplectic seizure. The loss of consciousness is rarely profound, and the symptoms of apoplexy soon pass off.

severe cases, however, they may deepen to fatal coma. Symptoms of irritation commonly succeed those of apoplexy as the collateral hyperemia sets in, or they may be marked at the onset. Convulsions, often unilateral, may occur and be repeated for days. The patient may pass from the apoplectic condition into one of delirium. In the old, delirium may be the chief symptom of the onset. According as these symptoms are chiefly marked at the onset three varieties have been described, the *apoplectic*, *convulsive*, or *delirious* forms.

Recovery from the special symptoms of the attack is often incomplete; permanent weakness may remain, as hemiplegia, and mental power is weakened, the patient passing into the chronic state about to be described. The persistent hemiplegia is often accompanied by rigidity, or by motile spasm, such as, in its most marked form, has been described as *athetosis*. Whether recovery is complete or incomplete, return or relapse is common, and is almost invariable where the arterial disease, to which the softening is due, is widely spread.

Chronic softening is a term applied to a group of symptoms, of wide range, indicative of failure of brain-power. These may supervene on more acute symptoms of softening, or may be gradual in their onset. There is mental dullness, defective perception, drowsiness, loss of memory (especially for recent events), often slight wandering; emotional manifestations are easily excited. The patient complains of headache, pains in the limbs, and feelings of 'numbness,' which may or may not be associated with actual loss of sensibility. Physical power is defective, usually generally, sometimes locally. The more delicate motor actions are imperfectly adjusted: articulation becomes confluent, and the handwriting indistinct or illegible. These symptoms may progress into actual imbecility, or may be cut short by some more profound cerebral seizure, or by some intercurrent pulmonary affection, rendered grave by the deficient muscular respiratory power. They depend upon degeneration of brain, commonly due to arterial disease. Spots of softening, often widely spread, may be associated with this condition, and may be, indeed, the cause of the symptoms. But the state may come on without any local softening; and atrophy of brain, with or even without degenerated vessels, may be the only anatomical condition. It often follows any grave local lesion—softening, hemorrhage, or tumour—and then depends on a direct prejudicial influence on the cerebral nutrition, or on a secondary effect through the perturbed vascular system.

DIAGNOSIS.—The *acute* form of softening has to be distinguished from acute congestive apoplexy and from cerebral hemorrhage. It is distinguished from the former by the persistence of the symptoms indicative of local mischief, and by the absence of evidence of cephalic hyperemia. From hemorrhage the diagnosis is often difficult. In softening from thrombosis, the initial apoplectic symptoms may be absent, or, if present, are slight and brief. They are more often preceded by symptoms of local cerebral anemia, due to the vascular disease, than is the onset of cerebral hemorrhage. Improvement occurs earlier than

in cerebral hemorrhage. The temperature rises soon after the attack, but falls in a day or two: in hemorrhage the rise occurs later (Bournoville). There is more marked mental change than in hemorrhage, shown at first in excitement, subsequently by depression and deterioration of power. In the cases in which the onset is sudden and the apoplexy profound, a diagnosis from hemorrhage is often impossible. In softening from embolism the patient is usually below middle age, heart-disease is present, and evidence of arterial disease is absent. The onset of the attack is commonly sudden, but the loss of consciousness is less profound than in hemorrhage. In capillary embolism, if extensive, a distinction from hemorrhage often cannot be made: the loss of consciousness is profound and lasting.

Softening may be distinguished from local cerebral anemia, which often precedes it, by the definiteness and persistence of local symptoms, but a small area of softening may produce symptoms identical with those resulting from a large area of anemia. Softening is distinguished from tumour and chronic meningitis by the slight pain and the absence of optic neuritis. From simple atrophy of the brain, *chronic* softening differs by its less uniform course, and by the sudden occurrence and persistence of symptoms indicative of local lesions.

PROGNOSIS.—The immediate and ultimate prognosis in an attack of softening of the brain depends on its severity in degree and extent, as indicating the extent of the lesion, and on the region of the brain damaged. Both the immediate and the ultimate prognosis is much graver in damage to the medulla and pons Varoli than when the corpus striatum or cerebral hemispheres are affected. Youth and general health favour the rapidity and the degree of recovery. Where actual softening has occurred, the damaged tissue probably never regains its functional power. The congested periphery recovers in proportion to the inherent vitality of the tissues, and to the freedom of the vessels from disease. The chances of a recurrence of softening in another situation depend on the extent to which its causal condition is widely spread or can be removed. In vascular degeneration recurrence is almost certain. In embolic softening there is usually organic valvular disease in the heart, and embolism recurs in a considerable proportion of the cases, though less frequently than senile thrombosis. The prognosis in syphilitic disease of the vessels depends upon the recognition and treatment of the syphilitic influence.

TREATMENT.—During an acute attack the patient must be kept at perfect rest, with the head moderately raised, in a uniform temperature. During the initial stage of shock, warmth, by hot-water bottles, &c., should be applied to the surface, to equalize the circulation. The bowels, if confined, should be made to act gently; but, unless the evidences of encephalic congestion are early and conspicuous, purgation should be avoided. Should stimulants be administered? It has been proposed by stimulation of the heart to aid the establishment of the collateral circulation. But it must be remembered that the imper-

feet collateral flow arises from the minute size of the arterial anastomoses. The obstruction of one vessel always increases the adjacent pressure to such an extent as to distend the vessels to their utmost strength, and any further increase would, by rupturing them, impede rather than further the object in view. If, therefore, the heart is acting feebly, stimulate it by small quantities of alcohol to the normal force, but not beyond. If the diagnosis from hæmorrhage be in any degree doubtful, great caution should be observed in stimulation. After the stage of depression has passed, the irritation due to collateral hyperæmia, and indicated by elevation of temperature, may be relieved by purgatives, dry-cupping, and even, in some cases, by the application of leeches, though the latter are only necessary when the evidence of general vascular irritation is great. When convulsion is an early and recurrent symptom, mustard plasters to the neck and extremities, and bromide of potassium in large doses, are useful.

After the attack has passed, recovery must be aided by maintaining the general health in the best possible condition. The secretions should be kept free, the digestive organs in good order, the habits strictly regulated, and nerve tonics, cod-liver oil, hypophosphite of soda, strychnine, quinine, and iron, may be given with advantage. The symptoms of chronic softening, whether occurring after an acute attack or coming on gradually, should be treated in a similar manner. Great care should be taken that the peripheral obstruction to the circulation, indicated by augmented arterial tension, (incompressibility of pulse), is kept at its minimum by the avoidance of excess in diet, and by prompt purgation when any increase in tension is observed.

W. R. GOWERS.

BRAIN, Syphilitic Disease of. See **BRAIN, Tumours and New Growths of.**

BRAIN, Tubercle of. See **BRAIN, Tumours and New Growths of.**

BRAIN, Tumours and New Growths of.—The intimate connection of the brain with its membranes makes it impossible, except in the most general terms, to draw any marked distinction between tumours of the cerebral substance, and tumours arising from its envelopes. A growth pressing inwards from a membrane must impinge upon brain-tissue: a growth originating in brain-tissue must in many situations involve the membranes.

ANATOMICAL CHARACTERS.—The tissues from which tumours have their origin seem to present the best ground for a scientific classification of these lesions: and it is not devoid of interest to mark that the absolute nerve-elements of the brain are never primarily the source of a morbid growth.

Cerebral tumours, then, may be roughly separated into three series:—

1. Those whose centre of origin is some one or other of the membranes, external to the brain, or dipping into the ventricles.

2. Those which spring from the blood-vessels.

3. Those which own the neuroglia as their starting-point.

Taking this subdivision, which is Rindfleisch's, the tumours which are placed in each series differ somewhat from his arrangement.

In the first series five kinds of tumours are found, arising from the membranes or from the free surface of the ventricles. These are *Pachionian granulations*; *spindle-celled sarcoma*; *neynoma of the membranes*; *psammoma*; and *lipoma*.

The second series will include, first, aneurisms, depending upon disease of one or more of the arterial coats; and, secondly, such tumours as have their origin in the sheaths of the vessels, comprising *carcinoma cerebri simplex*; *fungus of the dura mater*; *cholesteoma*; *epithelioma myxomatodes psammosum*; *papilloma of the pia-mater and vessels*; *papilloma myxomatodes*; and *tubercle*.

In the third series may be counted *glioma*; *myxoma of the nerve-substance*; *syphilitic gumma*; and *fibroma*.

Included under none of these headings, *echi nococi* and *cysticerci cellulose* must be mentioned, as they affect the brain.

Each of the growths enumerated will now be briefly described.

1. *Pachionian granulations.* These are granulations of the arachnoid, sometimes met with in childhood, very constantly from middle age onwards, and scarcely recognised as morbid lesions. Their ætiology is unknown. They do not give rise to any symptoms. They are chiefly situated along the superior longitudinal sinus, which in rare cases is perforated by them. They form groups of papillæ, consisting of striped connective tissue, poor in cells, and proceeding directly from a thin but a continually renewed layer of sub-epithelial germinal tissue.

2. *Sarcoma.* This sometimes has its origin in the nervous tissue itself, but more frequently arises from the dura mater, especially at the base of the skull. From their situation sarcomata are especially apt to interfere with one or more of the cerebral nerves. They may attain the size of a pigeon's, or even of a hen's egg.

When sarcoma attacks the dura mater it originates from its internal side. The most usual situation is the membrane about the sella turcica and the pars petrosa. It forms a depression in the brain, while the bone becomes atrophied behind it. The growth is composed of fusiform cells, with tolerably numerous, and sometimes dilated vessels. Sarcomatous growths are not freely developed above the surface, but rather in the depths of the tissue; they distend the cerebral convolutions, form deep depressions on the surface, and even penetrate far into the brain. They occur under two forms—*hard sarcoma* with compact fibrous fundamental tissue and small cells, often called fibrous tumour; and *soft sarcoma*, with a loose scanty intercellular substance, and numerous cells of comparatively large size. The cells are mostly fusiform, but sometimes round and multinuclear, and the two latter may be surrounded by the former. *Sarcoma* in this situation is generally single. It may attain the size of a nut or even of an apple, and is frequently hæmorrhagic.

In the cerebral tissue itself the hard sarcoma

attains a great degree of density: it is sometimes fibrous, at other times cartilaginous, of a dense homogeneous structure, whitish or bluish-white, with a yellow tinge here and there, and with very few vessels. It is distinguished from the brain that surrounds it by a very vascular zone. It can be easily separated from the parenchyma, and may thus be recognised after death from simple sclerosis and hard glioma of the brain. The softer form—fibro-cellular sarcoma—is generally either a myxo- or a glio-sarcoma: but pure fuso-cellular sarcoma is met with. The tumour is a clear grey, almost like the grey matter of the corpus striatum. It is often vascular, with a reddish tinge. These sarcomata are often almost spherical, and easily detached from the surrounding brain-substance. Others, however, seem to be continuous with the neighbouring tissue, and to be little more than simple hypertrophies of the cerebral tissue. Especially is this the case in tumours of the corpus striatum and optic thalamus. The cells of cerebral sarcoma are frequently the seat of fatty degeneration, and the whole tumour may be hemorrhagic. Its most frequent situations in the brain are the ganglia at the base.

3. *Myxoma*.—Myxoma of the membranes is rare, and generally has its origin from the convexity of the brain, being connected with the inner surface of the dura mater. It is a small growth, soft, fragile, having a gelatinous aspect.

Myxomata are frequently met with in the cerebral hemispheres, and then take their origin from the neuroglia. Such growths are probably malignant, the proof of their malignancy being that they are often multiple locally; that they frequently recur when removed from a peripheral nerve; and that they not seldom affect internal organs. Myxoma probably includes all that has been called colloid cancer. When this lesion affects the cerebral hemispheres it may be of large size. The mucus is a constituent part of the tissue; it is not a product of secretion, as in mucous cysts.

4. *Pneumoma*.—Pneumomata have been met with in the brain, spinal membranes, spinal cord, and nerves: they are not uncommon in the choroid plexus, but are most usually found in the pineal gland. There are two kinds of these growths. In the first, the sand occupies the interior of the meshes of the connective tissue in very varied forms, as compact cylinders, as pear-shaped masses, as spines, or as globes, surrounded by connective tissue, and connected by it with the other parts of the tumour. In the second form, the sand lies without cohesion in the parts and between them, so that the different grains of sand may be easily isolated. In this latter form, the pneumoma is composed most generally of round elliptical corpuscles, and sometimes also of large complex conglomerations. These little tumours have usually an internal concentric arrangement.

5. *Dipoma*.—This is a rare form of tumour. It may be connected with the inner surface of the dura mater, or with the ependyma of the ventricles. The fatty matter is contained in cells, and the cells are surrounded by an organised substance. *Dipoma* is usually single, seldom mul-

tipile; of irregular shape; and varies in size from a small nut to a hen's egg. Small pieces of carbonate of lime have been found in these tumours.

6. *Aneurisms*.—The larger cerebral aneurisms have been observed from early times. More recently Liouville has called special attention to the subject of military aneurisms, and has shown that they are common; that they are multiple; that they frequently give way in the brain or in the pia mater; and that they often co-exist with aneurisms of the larger vessels in other parts of the body. Aneurism of the middle meningeal, of the internal carotid within the cavernous sinus and at its exit from it, of the anterior cerebral, of the anterior communicating, of the arteries of the corpus callosum, of the middle cerebral, of the posterior communicating, of the vertebral, of the basilar, of the posterior cerebral, and of the arteries supplying the cerebellum, are all met with not unfrequently. The middle cerebral and the basilar, however, are the vessels most usually affected with this lesion.

The minute military aneurisms have been observed in the pia mater, at the surface of the convolutions or in their substance, in the optic thalamus, the pons, the corpora striata, cerebellum, crura cerebri, and medulla oblongata; more rarely in the centrum ovale. These military aneurisms may be visible to the naked eye. The smallest are seen under the microscope as ampulle of the vessels, containing coagulated blood or granules of hemoidin. The arterial walls have generally undergone some form of degeneration. The vessel, dilated at some parts, is constricted at others. The lesion may be a consequence of atheroma of the vessel, but far more commonly it is the result of arterio-sclerosis of the inner coat of the vessels, either at the seat or in the immediate neighbourhood of the aneurism. See BRAIN, Vessels of, Diseases of.

7. *Carcinoma cerebri simplex*. Cancer, excluding from this term sarcoma and glioma, may originate in the cranial bones, the dura mater, the pia mater, the cerebrum, the cerebellum, the pons, and the medulla oblongata. The medulla oblongata, the fornix, and the corpora quadrigemina, are the regions least often affected, whereas the cerebral hemispheres are the most favourite localities. All forms of cancer are met with, in all cases having their origin in the coats of the vessels. Epithelial cancer has been generally believed to have its starting point in the peripheral layer of the arachnoid, the tissue that lines the under surface of the dura mater. Encephaloid cancer is, however, the most common form met with in the brain.

8. *Fungus of the dura mater* can scarcely be separated from the preceding form. It arises from the outer surface of the dura mater, penetrates with the vessel from which it springs into the compact tissue, destroys the vitreous table, and spreads out in the diploe: in its progress it may penetrate the external table and lift up the integuments of the cranium. The internal table invariably suffers more than the external. Sometimes there is coincident passage of the tumour inwards, and the subjacent membranes become glued to the dura mater and to the cerebral substance. There may result simply

the depression of surface consequent upon pressure from above, but more commonly cell-growth similar to that of the original tumour takes place, first from the vessels of the pia mater, and afterwards from the vessels of the cerebral convolutions.

9. Closely allied to the epithelial cancer that has its origin in the dura mater is the *cholesteoma*, which is generally situated at the base of the brain. Rindfleisch considers it a squamous epithelioma, whose cellular cylinders are wholly converted into a mass of pearly nodules with a silky lustre. It is covered by the arachnoid, and springs either from the vessels of the pia mater, or more rarely from the perivascular sheath of the vessels in the substance of the brain.

10. Last of the cancers is a tumour that has been found in the third ventricle—*epithelioma myxomatodes pneumosum*, consisting of globes and cylinders of epithelial cells, embedded in a very bulky stroma of mucous tissue.

11. Springing also from the vessels, two forms of *papilloma* are met with—*papilloma* of the pia mater and vessels; and *papilloma myxomatodes*. The former is composed of a number of branching papillae, each of which contains a blood-vessel with a small amount of connective tissue, and a double coat of epithelium, of which the outer layer is columnar. In the latter, which is probably a mere variety of the former, the structure of the tumour is the same, but the columnar cells secrete a vast amount of viscid mucus.

12. *Tubercle* springs from the middle tunica of the small arteries of the pia mater, or of the nerve-substance. It rarely attacks the membranes in the form of tumour, rarely also the white matter of the brain, but prefers as its principal seat the grey matter of the convolutions and of the deeper parts. Tubercle of the dura mater is, however, sometimes met with, and it may induce obliteration of sinuses. The cerebellum is a frequent seat of tubercle, which exists here in the form of superficial granulations. The pons also is frequently affected with tubercle, both in the form of small tumours of its substance, and as polyposal tubercles of the fourth ventricle. Tubercle is separated from the surrounding cerebral substance by a very delicate reddish envelope.

Tubercular tumours of the cerebral substance are often multiple, and not unfrequently large; they are of very slow growth; persist long in the caseous state; and may be found encrusted. Sometimes there is cerebral softening around them. Virchow states that the increase of tubercles takes place by apposition or juxtaposition, and that the apposition takes place not by layers primarily caseous, but by zones of new grey proliferation, usually in the form of military tubercle. A very delicate layer of connective tissue of new formation, a species of encysting false membrane, represents the mother-tissue for the subsequent generation of young tubercles.

13. *Glioma*, called by Billroth *granulated sarcoma*, or *round-celled sarcoma*, is practically a local hyperplastic development of the neuroglia. It may appear in three forms, either as a *soft glioma*, rich in cells—the most common kind; as *hard glioma*, fibrous, and, if the vessels are much

developed, telangiectatic; or, thirdly, as a *myxoglioma*, a complex tumour, in which part of the tumour takes the appearance of mucous tissue. The nature of the tumour is partly determined by the nature of the tissue from which it springs; thus glioma of the brain is generally, but not always, soft; glioma of the ependyma hard. The soft gliomata are closely allied to myxomata. The intercellular substance is found in moderate quantity. In the more mucous gliomata the network is regular and large, and the tissue has little cohesion. If the meshes are larger still, and the mucous element abundant, this variety passes into a myxoma. If there be a considerable increase of cells, whilst the trabeculae become narrower, we get a medullary glioma, which may be transformed into a medullary sarcoma if the cells continue to grow and multiply. These transitions are not uncommon even in the same tumour, especially in the posterior lobes of the brain. If the vessels are developed in great abundance we get hæmorrhages and a kind of fungus hæmatodes. Hard glioma is closely allied to fibroma, with which indeed it may be combined to form a *fibro-glioma*. In hard glioma the fibres are not arranged in a network, but in parallel lines, like felt. The nervous elements, naturally contained in the neuroglia, are absent in these tumours. The walls of the vessels are frequently thickened.

The glioma of the ependyma is of little importance; it is seen as fine granulations on the surfaces of the lateral ventricles in chronic hydrocephalus; on the floor of the fourth ventricle it may grow to the size of a cherry. In the cerebral substance, gliomata may attain the size of a fist, or even of a child's head; and they are often mistaken for cancers or sarcomata of the brain. Hard glioma may be distinguished from sclerosis, in that sclerosis encloses the normal nerve elements. In glioma, too, there is great proliferation of neuroglia cells. There is no distinct limit between glioma and the surrounding brain-substance, but the tumour on section shows greater vascularity, greater consistence, and a more transparent constitution, as well as often a bluish-white appearance compared with the white brain-matter. The demarcation in grey matter is imperceptible to the naked eye, especially if the glioma be soft. Soft glioma is generally single; hard is often multiple. The membranes may adhere, but form no part of the tumour.

Virchow thinks that glioma is not malignant; that hard glioma has an inflammatory origin, and that the soft variety is set up by local causes, such as injury. Gintroe, on the other hand, unites gliomata and sarcomata under the head of cancers.

Soft glioma is most frequently situated in the posterior lobes, less often in the upper and lateral parts of the cerebral hemispheres. It may be congenital. It gives rise to complications, namely, first, great congestion, causing cerebral compression, irritation, pain, excitement, or apoplexy; and, secondly, hydrocephalus of the ventricles, which in protracted cases is seldom absent. The latter occurs most rapidly in glioma of the optic thalami, or of the posterior lobe, compressing the choroid veins, the vena Galeni, or the transverse sinus.

14. *Myxoma of the nerve-substance*.—This is not common in the brain. It owns the same origin as glioma, having the neuroglia as its starting point.

15. *Syphilitic gumma*.—Gummy tumours of the brain are generally found at the circumference, and especially at the base of the brain. Their origin is either from the membranes, from the vessels, or from the neuroglia of the cerebral substance. They have infective properties, or at any rate they are multiple, and may be met with at the same time affecting the dura mater, the pia mater, the brain, nerves, and cranial bones. They are often accompanied by inflammatory phenomena, a point which distinguishes them from large tubercles. Gumma is not the usual form in which syphilis attacks the dura mater on its external surface. It may, however, affect the arachnoid surface of the dura mater. In this situation the gummata may vary in size from a hemp-seed to a nut. They may be found just above the convexity of the hemispheres, or at the anterior part of the base of the brain, especially about the sella turcica, or on the tentorium cerebelli. They have been met with in the falx cerebri. The inflammatory condition around these tumours often unites them to the pia mater, and the subjacent portion of brain is frequently softened, either by the inflammation, or by arterial obliteration.

When the pia mater is united to the dura mater, gummata very small in size may form in the former membrane. The subjacent brain may be softened or sclerosed. Much larger gummata, however, from the size of a nut to that of a hen's egg, originate from the pia mater, and are most usually situated in the region between the optic chiasma and the pons, or on the crura cerebelli. On the convex surface they are much smaller. Gummata of the cerebral substance occur in situations most subject to traumatic influences. The chief seats are the cerebral hemispheres, the large ganglia, especially the optic thalami, and next in frequency the pons, and crura cerebri and cerebelli. The tumours attain to a good size, but are not so large as those of the pia mater. They may be multiple, but often exist singly. *See* BRAIN, Vessels of, Diseases of.

16. *Fibroma*. True fibromata, distinct from hard gliomata and sarcomata, probably do not exist in the brain or its membranes. Fibromata are essentially composed of connective tissue. Such increase in this tissue is sclerosis, and its arrangement is too indefinite, its amount too small, to be considered a tumour. Rindfleisch is probably wrong in stating that there are solitary tubercles of the brain which deserve rather to be called fibroid tumours; although it may be true that in some cheesy nodules of the necrosed centres the growth of fibres and the condensation predominate enormously over the suppurative structure. Practically, however, both *enchondromata* and *osteomata* are fibrous compounds. An *enchondroma* is a heterologous tumour not developed from a pre-existing cartilage, but produced by a change in the type of formation by succeeding from a non-cartilaginous matrix. Although *enchondromata* may be malignant, yet true *osteomata* are not so. These

tumours may attack the cerebral dura mater, and on the convexity are multiple. If the tumour attack the falx cerebri it is solitary. Its starting-point is the internal surface of the dura mater. It is distinguished from exostosis of bone by having a fibrous layer between it and the bone. It may set up irritative pachymeningitis. Such tumours also are found small in connection with the cerebral arachnoid, as simple united patches or pointed prolongations. Their favourite seat is the convex surface of the anterior lobes. The nervous centres are very rarely the seat of these tumours. Their matrix is formed by connective tissue, not cartilage, the product of irritation of the neuroglia, and so a consequence of circumscribed encephalitis.

17. *Hydatids* are rare within the skull, but are met with occasionally in all parts of the brain, between the membranes, in the ventricles, and lying free at the base of the brain. They are more common in children than in adults. The brain may suffer from pressure either in the way of softening from interference with the vessels, or from sclerosis.

Cysticerci are also met with in various parts of the brain or its membranes. They may be surrounded by connective-tissue capsules; or may lie free, arranged in a racemose form. They may be single, or may attack the same individual in several hundred places at once.

SYMPTOMS.—Even in tumours of considerable size all symptoms may be latent. The more tolerant portion of the brain will include the hemispheres and the white commissural regions, whilst the mesencephalon, the optic thalami, and the corpora striata are amongst the least tolerant portions. It is not unusual, moreover, to meet with decided intermissions, especially in the early period of the disease; such intermissions depending on temporary lesions in the immediate neighbourhood of the tumour.

Even with these intermissions the diagnosis of the presence or position of the cerebral tumours would be comparatively easy, if the symptoms invariably depended upon direct excitation. Many of the phenomena pass the limits of the immediate sphere of the tumour, and are the results of reflex action. Sometimes also the symptoms due to direct and reflex excitation may coincide, and this is particularly the case in tumours of the base. The main difficulties lie in the possible latency of all symptoms; in their intermission; in the distinction and combination of direct and reflex excitation; and in the remissions following physical or psychical excitement.

Symptoms then may depend on direct or reflex excitation, and consist of exaltation of functional activity, such as contractions, partial or general convulsions, hyperæsthesia, and hyperidæation. Others are produced by secondary lesions in the neighbourhood of the tumour—congestion, hæmorrhage, inflammation, &c.—and these may include not only all in the previous division, but temporary or persistent paralysis, fever, and other phenomena. Then there may be symptoms of direct compression, definite paralysis, and gradual enfeeblement of the sensorial and intellectual faculties.

*Taking some of the more common conditions in

order, and viewing them as dependent on direct or reflex irritation, the most frequent certainly is headache; and except a tumour of the cerebellum, when the headache is almost invariably occipital, there is no symptom less useful in determining the position of the lesion. It is less frequently due to direct excitation than to reflex. The pain is very severe, indeed, more so than in any other disease, excepting, perhaps, meningitis: it persists through the whole malady; and is increased by vibration of all kinds, light, sound, or movement of the head. It may be confined to a single spot, or be diffused over the whole head. Connected with headache in many cases, and often equally the effects of radiated influence, are tinnitus aurium, morbid acuteness of hearing, and painful sensitiveness to sound; disturbances of vision, diplopia, muscæ volitantes, and strabismus, which may be transient; formation, and sometimes hyperæsthesiæ of greater or less extent. In some cases there is an agitated condition of the intellectual faculties, and even delirium. Disturbances of sight are very common. The retinal lesions will be subsequently described. It is a remarkable fact, as bearing upon reflex phenomena, that the affections of sight usually implicate both eyes, even where the tumour has involved only one optic nerve, and is not situated near the optic chiasma or the corpora quadrigemina. Hearing is far less often affected than vision. Generally a slight diminution only of this function is observed; and, in the rare cases in which complete deafness is met with, it is unilateral. Taste and smell are seldom interfered with. When these special senses are morbidly affected, the tumour in the first case will probably be located in the posterior portion of the base; in the second at the anterior half of the base of the brain.

The symptoms of compression may be included in the expression 'lowering of function,' comprising apathy, feebleness of memory, want of attention, confusion, and a general enfeeblement of ideas. These conditions are often accompanied or preceded by certain diffused symptoms, such as vertigo.

Vertigo is the first symptom in many cases: it is felt especially when the patient is in the upright position. It often produces uncertainty of gait, even where the tumour is not in the cerebellum. Strange sensations in the head are also complained of, a feeling of liquid in the head, or of a mobile body; or the sensation may be that of a solid body filling the head, or pressing upon some portion of it.

These phenomena often coincide with evidences of irritation of the meninges, whether due to direct compression or to radiated irritation of the medulla oblongata. Chief amongst these symptoms is vomiting. It is not accompanied by nausea or other manifestations of dyspepsia, and it will occur when the stomach is empty. It can frequently be checked only by keeping the patient in a recumbent position. Constipation also is often obstinate.

Epileptiform convulsion has an important bearing on the diagnosis of these lesions. Very frequently convulsion is preceded by many of the phenomena already touched upon, such as headache or vertigo. Frequently, however, convul-

sion precedes all other morbid phenomena, and the patient may be in perfect health in the intervals of the attacks. Given, therefore, convulsion as the one factor in forming an opinion, it is necessary to consider the liability of the patient to convulsive attacks from causes other than tumours; to realise whether the family history shows any suspicion of epilepsy; and to eliminate from the case the possibility of saturnine, alcoholic, and uremic poisoning. If this is done, and especially if we find early convulsions associated with headache and with vomiting, this symptom will prove an important aid in the diagnosis of tumour.

The phenomena depending on the presence of tumour itself may be associated with others due to complications, such as oedema, congestion, encephalitis, or meningitis of the surrounding parts. A high temperature, for instance, will point to inflammation either of the nervous substance or of the meninges near the lesion; and meningeal inflammation seems to be accompanied by the highest temperature. Syphilitic gumma, however, may coincide with syphilitic meningitis on some other portion of the encephalon not directly connected with the immediate surroundings of the tumour.

Passing for the moment the subject of definite paralyses with the remark that the sphincters are seldom affected, even in cases in which the paralysis takes a paraplegic form, it may be mentioned that a want of equilibrium seems to be a not unusual evidence of the presence of tumour in the cerebellum. Aphasia may not only be due to the special localisation of tumour in Broca's region of the left anterior lobe, but also to the presence of this lesion in any part of the track (corpus striatum, optic thalamus, or crus cerebri) which unites this portion of the hemisphere to the medulla oblongata, the highway by which the centre for the production of articulate speech is connected with the co-ordinating centre for this function. Anæsthesia of the skin is seldom met with as a symptom of cerebral tumour. When present it is found only in the limbs affected with motor paralysis, and is scarcely ever complete.

Symptoms of special localities—It remains to take special regions of the encephalon separately and to endeavour to differentiate the position of the tumour by the symptoms attending its presence.

Tumour in the *medulla oblongata* will be accompanied by various disturbances of sensibility, especially headache, and sometimes by convulsions. The pressure of a tumour is seldom limited to the medulla oblongata, and the symptoms therefore are complex. In several of the cases recorded there has not only been amaurosis and deafness of one side, but interference with taste and smell.

Tumour of the *fourth ventricle* may manifest itself by the presence of sugar or of incrusts in the urine. Tumour here, as in the medulla oblongata, frequently destroys life quickly, before there has been time, so to speak, for much local lesion to be set up. Vomiting is a frequent symptom.

Tumour of the *crus cerebri* and of the *corpora quadrigemina* cannot be diagnosed by any peculiar symptoms. In one case, in which the

corpora quadrigemina seemed wholly transformed into a tuberculous mass, the sight remained good, but there was double ptosis.

In tumour of the *cerebrum* there is little disturbance of sensibility except occipital headache. There are various disturbances of motility, especially convulsions and irregularity of locomotion, but no true paralysis. Amblyopia, amaurosis, and convergent strabismus are common. There is no interference with the psychical functions, or with speech, as a general rule. Vomiting is very common. In 76 cases collected by Ladame, there was no abnormality in the genital functions, except in four instances.

In tumours of the *pons*, the disturbances of sensibility are general or partial anæsthesia, and in some cases more or less headache. Hemiplegia of unequal degree on the two sides, and other forms of paralysis are observed, but no convulsion. Various and manifold disturbances of the special senses; phenomena of depression of mind; frequent alteration of speech; and early disorders in swallowing occur.

Tumours of the *crura cerebri* follow the example of the same lesion in the pons with reference to disturbances of sensibility. Equilateral hemiplegia opposite to the lesion is met with, and paralysis of the oculo-motor nerve on the same side as the tumour, often gradually extending itself to both oculo-motors.

Tumours of the *pituitary gland* are accompanied by intense frontal headache; by no definite disturbances of sensation or of motion; by double amblyopia or amaurosis, unequally developed; and by no loss of speech.

Tumours of the *middle cavities of the cranium* seem to affect mainly the third and the fifth nerves, anæsthesia or pains in the face and ptosis being the prominent symptoms, with some interference with the free action of the other muscles of the eyelid supplied by the third. In one case, in which a scirrhous tumour of the left side was situated on the inner surface of the sphenoid bone, extending laterally to the internal auditory meatus and backwards to the pons, not only were the third and fifth nerves paralysed, but colour-blindness supervened some time before death.

In tumour of the *corpora striata* and *optic thalami*, headache is less frequent than in other regions. Hemiplegia and convulsions are frequent, the former especially so. Hardly any disturbance of the special senses is observed. Intelligence and speech are frequently disordered.

In tumour of the *corpus callosum*, there is frequently some mental aberration, and often convulsions.

In tumour of the *middle cerebral lobes*, headache is frequently a prominent symptom, but otherwise the sensory disorder is mainly anæsthetic. Hemiplegia is common, as is also convulsion of an epileptiform character. These convulsive attacks are not rarely unilateral, and sometimes affect at first one limb only. In fact the position of a tumour towards the anterior portion of the middle lobe may be determined by symptoms with tolerable accuracy. Various disturbances of sight and of hearing are met with; as well as various psychical abnormalities, ranging from mere confusion of ideas to absolute imbecility.

In tumour of the *anterior lobes* there is general headache, seldom of the frontal region particularly. No other sensory disturbance occurs. Sight and smell are frequently affected, speech seldom. Hemiplegia, convulsions, and psychical disturbances will occur much as in tumours of the middle lobes.

In tumour of the *posterior lobes*, there is general headache, seldom localised in the occiput; no other sensory disturbance. Slightly marked hemiplegia occurs, and convulsive attacks are very frequent. There is no disturbance of the organs of special sense. The mental faculties are greatly altered, particularly in the tendency to depression.

All three lobes may be affected with tumour coincidently, and the headache is then very intense; the epileptiform convulsions exceed the paralytic phenomena; the organs of special sense are little affected; and there are various mental disturbances.

In tumour of the *convexity*, the headache is generally limited either to the frontal regions, to one side of the head, or to the occiput. There is neither anæsthesia, nor paralysis, but intense convulsions occur. The special senses are not disturbed. The mental condition is one of irritation, evidenced by delirium and excitement.

Lastly, very various regions of the brain may be simultaneously the seat of tumour, and the morbid phenomena will be necessarily complex.

Retinal changes.—It has seemed more convenient to speak of retinal changes dependent on cerebral tumour separate from the other symptoms. Great variations in the lesion occur according to the position of the tumour; its direct interference with the optic centres; its complication with meningitis; and its pressure on the optic nerves and chiasma.

Taking choked disc, optic neuritis, and atrophy of the optic nerve as the three chief lesions, cerebral tumour may very frequently induce choked disc, by interfering with the venous ebb from the eye; optic neuritis, if meningitis is associated with the tumour; optic atrophy, by pressure of the tumour on the optic nerve, or by this pressure of the tumour or of hydrocephalus secondarily induced by it on the optic centres or tracts, or by softening around the tumour, such softening implicating the optic centres, or, lastly, by the propagation of sclerosis. Any tumour situated far back in the encephalon may interfere with the venous flow through the veins of Galeni, and so produce hydrocephalus of the ventricles, and the retinal effects of hydrocephalus.

There are no retinal changes from tumour in the corpus callosum, nor as a rule from tumour in the optic thalami. Tumours of the cerebral hemispheres all influence the optic nerve, if they interfere with the base of the brain.

Tumours of the cerebellum may cause pressure on the lateral sinuses, the straight sinus, the veins of Galeni, or the torcular Herophili; pressure in any of these situations may produce choked disc. Or the tumour may affect the *corpora quadrigemina*; or softening around it may spread to these organs, and atrophy of the optic nerve be the result. *A fortiori*, tumour

of the corpora quadrigemina themselves will lead to atrophy of nerve.

Tumour of the crura cerebelli causes hydrocephalus, and its effects on the retina.

In a similar way tumours springing from the bone or the membranes at the base of the brain may produce choked disc or atrophy, according to the position of the pressure, optic neuritis by complications with meningitis, or neuro-retinitis by irritation of the connective elements of the nerves. See OPHTHALMOSCOPE IN MEDICINE.

COURSE.—The clinical course of cerebral tumours is intermittent and paroxysmal. In many cases, such as those of glioma, it is very slow. Two groups of phenomena may complicate its ordinary course, namely, those associated with meningitis and apoplexy.

SPECIAL TUMOURS.—Aneurismal tumours may sometimes be distinguished by the sense of throbbing in the head; by the patient being of adult age or young; by his being attacked in the midst of perfect health; by vomiting being rare, apoplexy frequent, paralysis of cranial nerves early and unilateral, and by absence of mental phenomena. Aneurism situated in the cavernous sinus produces exophthalmos. See next article.

The symptoms of echinococci differ very little from those of other slow tumours: headache, dizziness, vomiting, syncope, and epileptiform attacks are most frequent. Disturbances of the motor and sensory functions, and also of the mind itself, are sometimes met with, and vary according to the situation of the lesion. The prognosis is unfavourable; the diagnosis impossible, unless echinococci exist at the same time in the liver.

Cysticerci manifest their presence in the brain by epileptic attacks, which augment in number and severity; the health of the patient between the fits is at first good, then apathy and torpor supervene; hemiplegia is rare, and never early; cranial nerve paralyses are exceptional; the symptoms are diffuse and bilateral, owing to the position of the parasite in the grey convolutions, and in many spots at a time. The age of the patient is above 40. Perhaps there may be evidence of the presence of cysticerci elsewhere.

Syphilitic tumours coincide with actual or previous syphilis. The headache attending this form of tumour is generally intensified at night.

Tubercle of the brain there is often a tuberculous family history, or the presence of tubercle elsewhere in the body. It seldom compresses cranial nerves. Its clinical evolution is often by paroxysms, and grave cases are combined with tuberculous arachnitis and hydrocephalus of the ventricles. Tubercle in the cortical substance of the brain and cerebellum may, however, be attended by no special symptoms.

In cancer also there is frequently a family history of this malady; and the cancerous cachexia may be present. Cancer seldom exists elsewhere when it is cerebral. This growth is much less often accompanied by symptoms due to congestion and hæmorrhage than glioma or sarcoma, being less vascular.

PROGNOSIS.—The prognosis of cerebral tumour is always bad, except in syphilitic gumma, and perhaps aneurism.

TREATMENT.—In syphilitic gumma and in aneurism large doses of iodide of potassium may be used with more or less success. This remedy is also useful in dispersing the results of the meningitis which so often accompanies tumour of the base. Beyond this there is little to be done, except in the endeavour to relieve pain and to support the strength of the patient.

BRAIN, Ventricles of, Diseases of. See VENTRICLES OF BRAIN, Diseases of.

BRAIN, Vessels of, Diseases of.

1. Aneurism.—The larger arteries of the brain, and their minute branches in the cerebral substance, are both liable to aneurismal dilatation.

(a) *Aneurism of the larger cerebral arteries* is more common than that of vessels of a similar size elsewhere. The large vessels of the base, or their primary branches, may be affected. The basilar and middle cerebral arteries are those most frequently diseased, aneurisms of those two vessels constituting three-fourths of the cases. Next in frequency is the internal carotid. The vertebral, anterior and posterior cerebrials, anterior and posterior communicating, and anterior cerebellar arteries are occasionally, but less frequently, involved. In one or two recorded cases the aneurism has been situated in the interior of the pons Varolii or cerebellum. The arteries of the two sides of the brain are affected with equal frequency, with the exception of the middle cerebral, which, with its branches, suffers twice as frequently on the left side as on the right. There may be more than one aneurism, situated on different arteries or on different branches of the same artery. The aneurism is usually sacculated, rarely dissecting. Its size varies from that of a pea to that of a nut, but aneurisms of the anterior or middle cerebrials have attained a much larger size. When this is the case the brain-tissue is pressed upon and softened.

ÆTIOLOGY AND PATHOLOGY.—These aneurisms are rather more common in men than in women. They occur at all ages, being more frequent before the ordinary degenerative period than aneurisms elsewhere. Nearly half the recorded instances have occurred between ten and forty years, and about one-seventh between ten and twenty. The change in the arterial wall resembles that giving rise to aneurism elsewhere—a fibroid degeneration, with loss of muscular and elastic tissue. This may be part of a widely spread arterial change, or more frequently is local. When local, it is sometimes due to syphilitic disease of the arterial wall, but still more frequently to the consequences of embolism. Dr. Church first pointed out the frequent association in young persons of cerebral aneurism and valvular disease of the heart, and many facts have been published which support the hypothesis that the aneurism in these cases may be the consequence of incomplete obstruction by embolism. There is also evidence of inflammatory and degenerative changes (thickening, calcification) in the

wall after embolism, especially when the plug comes from an inflamed endocardium. If the obstruction is incomplete, the altered wall may yield to the blood-pressure. In harmony with this theory are the frequent absence of degeneration in other arteries, the frequency with which the left middle cerebral is the seat of the aneurism, and the occasional occurrence of several aneurisms on branches of the same arterial trunk. The efficient agent in the production of the aneurism is the high blood-pressure in the cerebral arteries.

Rupture has occurred in about three-fourths of the recorded cases of cerebral aneurism. The blood may escape rapidly or slowly, and the hemorrhage may take place into the subarachnoid space, or into the adjacent cerebral substance. In the former case, meningeal hemorrhage is the result. Rupture into the cerebral substance is not uncommon. An aneurism in the fissure of Sylvius may cause a hemorrhage into the substance of the brain, bursting into the lateral ventricle; and an aneurism on the posterior cerebral artery may burst into the substance of the pons. Two causes may determine this rupture into the substance of the brain—first, thickening of the subarachnoid tissue adjacent to the aneurism, hindering its rupture outwards; secondly, the gradual escape of the blood, producing a slow disintegration of the brain-tissue, and thus preparing a channel for the effusion. In such cases only a small quantity of blood may have trickled into the ventricles or subarachnoid space. In rare cases a communication with a sinus forms, and constitutes an arterio-venous aneurism. This has occurred between an aneurism of the internal carotid and the cavernous sinus.

SYMPTOMS.—Symptoms of the existence of an aneurism may be entirely absent. When present they depend on the pressure which the tumour exerts on neighbouring parts. They vary widely according to its seat, and they are rarely by themselves distinctive. Mental disturbance is uncommon. Headache is a very uniform symptom. It is often intense, sometimes throbbing, and may be localised, as in the occiput in basilar aneurism. Convulsions occur in some cases, and are said to be more common when the disease is near the medulla. Paralysis are frequent, and depend on the pressure of the tumour: the most common are those of the cranial nerves which lie adjacent to the aneurism, as of the nerves of the orbit in aneurism of the internal carotid. Such symptoms are suggestive of an aneurism when they indicate pressure in the known situation of a vessel. In some cases a murmur can be heard by the patient, and in still rarer cases (of aneurism of the internal carotid) it has been audible on auscultation. Aneurism elsewhere may increase the probability that an intracranial aneurism is present, and so, in the young, may valvular disease of the heart.

Rupture of cerebral aneurism gives rise to symptoms which vary, as in rupture of aneurisms elsewhere, according as the blood escapes quickly or slowly. If quickly, the blood usually escapes into the meninges and causes sudden paralysis with general paralysis, rapidly deepening

into a fatal issue. If slowly, the symptoms are less sudden, and unilateral paralysis or convulsion may occur. This is especially the case when the blood escapes slowly into the cerebral substance, unilateral symptoms occurring, and gradually increasing during a few hours or days, with or without initial loss of consciousness, but ending in fatal coma.

TREATMENT.—Little can be done in cases where intracranial aneurism is suspected. Even when it is of syphilitic origin, drugs can only partially restore the damaged and dilated vessel. Hypodermic injection of ergotin (½-grain) has been recommended by Langenbeck and advocated by Bartholow. Iodide of potassium may also be given. Rest is important. All causes of increased intra-cerebral pressure, such as effort and low positions of the head, are to be avoided. The bowels should be kept regular. In rare cases where progressive paralysis of orbital nerves suggests the probability of aneurism of the internal carotid, and a murmur renders the diagnosis certain, ligature of the common carotid may be, and has been, resorted to with success.

(b) *Minute 'milinary' aneurisms* occur in the small arteries of the pia mater and substance of the brain (Virchow, Charcot and Bouchard). They are found at all ages, but more frequently in the old. They may involve vessels not more than the $\frac{1}{100}$ inch in diameter, but are most common on vessels a little larger than this; the walls suffer fibroid degeneration of the outer and middle coat, commencing, it is said, as nuclear proliferation. The muscular tissue of the middle coat disappears, and the whole wall at the spot becomes dilated into a sacculated aneurism, varying in size from the $\frac{1}{100}$ to the $\frac{1}{50}$ of an inch. These dilatations have been found in all parts, but most frequently in the optic thalamus, and next most frequently in the pons Varolii, the convolutions, the corpora striata, the cerebellum, the medulla oblongata, the cerebellar peduncles, and the conus medullaris (Bouchard). They often rupture and cause minute hemorrhage. They are found frequently in cases of large cerebral hemorrhage; and Charcot and Bouchard believe that such hemorrhage is frequently due to their rupture. Liouville has pointed out that minute aneurisms of the retinal arteries sometimes co-exist.

The rupture of a minute artery into its perivascular sheath distends it with blood, causing what has been termed a minute dissecting aneurism. Such are frequently met with in cases in which the vessels are exposed to extreme pressure, as in death from asphyxial conditions; or in the increased tension in collateral vessels when vascular obstruction has occurred.

No symptoms are known to be associated with the existence of these minute aneurisms. The symptoms of rupture are described under 'BRAIN, Hemorrhage into.'

2. *Degeneration. (a) Of Arteries.*—The larger cerebral arteries are very common seats of the thickening of the inner coat, called by Virchow 'Endarteritis deformans,' and which when fatty degenerated, constitutes 'athroma.' On the cerebral vessels the fatty change occurs quickly and frequently; and opaque yellow

thickenings are the result. Only one or two of these may be present; or the change may involve the whole of the larger vessels at the base and extend for a considerable distance along the chief cerebral branches. The distribution of the degeneration may be symmetrical. It may coexist with a similar change in arteries elsewhere, or may be isolated. Degeneration of the cerebral arteries is common after middle life, being found in seven-tenths of the subjects examined (Bichat). It occasionally occurs much earlier, especially in cases of chronic Bright's disease. Bright's disease and alcoholism are its chief diathetic predisponents. The exciting cause of this disease is probably the strain to which the badly supported cerebral vessels are exposed. It is not easy to explain their occasional freedom from atheroma when this is abundant elsewhere. The degenerated patches rarely soften and open into the vessel, so as to permit the formation of a dissecting aneurism. More commonly they undergo calcification. The result of these nodular degenerations is to lessen the calibre of the vessel, sometimes to close it altogether, and to favour the formation of a conglum. The lessened area of the vessel causes local anæmia of the brain. If the vessel becomes occluded, or if conglutination takes place in it, softening occurs in the part supplied by it. Where the degeneration has led to only slight thickening of the wall, the artery may be dilated at the spot. The degenerated vessel may burst under the pressure of the blood and hæmorrhage result. The minute arteries of the cerebral substance undergo similar changes, less conspicuous from their smaller size. Fatty degeneration of the cells lining the perivascular sheath is common at all ages. Under circumstances similar to those in which the larger arteries degenerate, all the coats of the small vessels suffer. Simple fatty degeneration of the middle coat occurs also at all ages. Miliary aneurisms may be formed, or rupture occur, as a consequence of these changes.

SYMPTOMS.—Atheroma of the cerebral vessels leads to the symptoms of local anæmia of the brain, and is a common cause of the transient cerebral symptoms so frequent in the old.

TREATMENT.—Tonics, cardiac stimulants, and substances which, as cod-liver oil, promote the nutrition of the nerve-tissue, are the most useful remedies.

(b) *Of Veins.*—Degeneration of the walls of the veins is much less frequently observed than degeneration of the arteries, perhaps on account of the less degree of pressure to which they are exposed. Occasionally the veins of the pia mater may be found varicose in advanced life, and in one case recorded by Andral rupture of such a dilated vein was the cause of meningeal hæmorrhage.

3. **Embolism.**—**DEFINITION.**—The obstruction of arteries or capillaries of the brain by solid particles carried by the blood-current from some other part of the vascular system.

ÆTIOLOGY.—The source of the embolic particles is almost invariably situated between the pulmonary capillaries and the obstructed vessels, i.e. in the pulmonary veins, the left side of the heart, or the arteries. In arterial embolism it is

necessarily so, since no particles large enough to obstruct even a small artery could pass through the capillaries of the lungs. In almost all cases the heart is the source of the plugs, a particle of fibrin being washed by the blood from a deposit on a diseased valve or in some recess (as the auricular appendix). Endocarditis, or chronic valvular disease, therefore, usually coexists with the embolism. Mitral stenosis is an especially frequent source of emboli, probably because the surface is commonly much altered, and the blood-current is in part slow (in diastole, allowing deposit), and in part very rapid (in auricular systole, detaching loose fibrin). Disease of the aorta—atheroma or aneurism—is the next most frequent source, and, less frequently, disease of the carotid or vertebral arteries, and conglutination in the pulmonary veins, large or small—the latter in some rare cases of inflammation and growths.

Particles obstructing capillaries may come from some softened atheromatous patch or fibrinous deposit, from pigmentary formations, or from deposits in ulcerative endocarditis. In the last case the obstructing material has a septic character, and the inflammation it causes may be suppurative.

ANATOMICAL CHARACTER.—Almost any of the cerebral arteries may be obstructed, the internal carotids and middle cerebrials or their branches most frequently, the anterior cerebrials or the basilar less frequently, and the posterior cerebrials still less frequently. Obstruction of several vessels is sometimes found, having occurred at the same or at different times. The cerebral arteries of the two sides are plugged with nearly equal frequency; the internal carotid much more frequently on the left side than on the right. It seems that a large fragment is influenced in its course by the more direct path through the left carotid, while smaller fragments find their way with almost equal readiness to either side. The middle cerebrials are very frequently affected, sometimes on both sides; and, when the bilateral symmetry of the vessels is great, each may be obstructed at the same place.

The plug is usually arrested at some spot at which the vessel is narrowed by a branch being given off. Here the fragment may be found, usually decolorised, and commonly closing altogether the lumen of the vessel. On each side of this is a secondary clot: the distal extends far into the contracted branches of the vessel, the proximal as far as the next large branch. The obstruction may lead to inflammation of the wall of the vessel at the spot, especially when the plug has been carried from a place at which inflammation is going on. The inflammation leads to change of texture and degeneration, fibroid or fatty; the former may permit an aneurism to be formed, the latter may cause a thickened patch, in which calcification may occur. The inflammation may spread to the adjacent tissue, leading to induration around the spot.

The first effect of embolism is to arrest the blood-supply to the part to which the artery is distributed. It is only when the obstruction is beyond the circle of Willis that cerebral structure (softening) follows.

occurs more uniformly in obstruction of the arteries of the central ganglia than in those of the convolutions. Capillary embolism also causes softening, and when the obstruction is from a septic source, 'metastatic abscess' may result.

For the SYMPTOMS, DIAGNOSIS, and TREATMENT of cerebral embolism see BRAIN, Softening of.

4. Rupture.—Rupture of cerebral arteries is common and is the cause of cerebral hemorrhage, and rupture of capillaries is not unfrequent. Rupture of veins is extremely rare, except as the result of injury.

(a) *Of Arteries.*—The proximate causes of rupture are weakening of the arterial wall, and increased pressure within the vessel. The conditions which give rise to these two factors are the remote causes of rupture. The actual rupture is commonly due to a temporary sudden excess of intravascular pressure.

ETIOLOGY.—The wall of the vessel is weakened, especially by degenerative disease—chronic periarteritis, or (rarely) simple fatty degeneration. Aneurismal dilatation and thinning may have resulted from the chronic change. In some diseases attended with a tendency to extravasation (purpura, hemophilia, &c.) it is conjectured that the vascular walls have undergone rapid degeneration, or are unusually thin. Defective external support, from atrophy of the brain, causing increased size of the perivascular canals, was formerly thought to be a potent cause, and is now perhaps underrated. The mobile perivascular fluid which surrounds the vessels must afford a less efficient support than cerebral tissue.

When vessels are much weakened, they may rupture when the extravascular pressure is at, or even below, the normal; very commonly, however, there coexists increased pressure. Loss of arterial elasticity leads to a jerky pressure. Arterial degeneration, and still more constantly, arterial contraction, in Bright's disease, cause increased tension by obstruction; and the hypertrophy of the heart, which develops to overcome the obstruction, adds materially to the pressure within the arteries. Hypertrophy to overcome an obstacle near the heart has probably no influence in causing rupture of cerebral vessels.

The instant cause of rupture is generally some temporary increase of the blood-pressure due to effort—as in cough, straining at stool or vomiting; excited action of the heart; suddenly developed heart- or lung-disease obstructing the circulation; local obstruction to return of blood; contraction of the arterioles, general or local; or the action of gravitation in the recumbent posture. The last two causes probably acting together determine the frequent occurrence of rupture during sleep.

The conditions which produce these proximate causes are the remote causes of rupture. The most efficient are those which determine weakening of the vascular wall, and have been already spoken of (see DEGENERATION). Age is an important element—rupture is most common after fifty, but may occur from local vascular disease at any age. Hereditary predisposition is seen in a tendency to early degeneration. Position of degeneration is probably largely influenced by

the distribution of the vessels: and the latter may be strikingly hereditary, as the retina sometimes shows. Sex tells probably by exposure to the greater pressure entailed by muscular effort (men suffer from rupture twice as frequently as women). Alcoholism leads to early degeneration. But the most efficient predisponent is Bright's disease, which leads to great intravascular pressure, and weakens the cerebral vessels by causing degeneration. It is probable that some acute diathetic diseases in which rupture is common act in a similar manner.

Certain of the cerebral arteries give way more frequently than others, especially the arteries of the corpus striatum and *pons Varolii*. This seems due (1) to their origin at right angles from vessels of very considerable size (basilar and middle cerebral), and their consequent exposure to the full pressure within the parent trunk. (2) To their 'terminal' character, which precludes collateral relief (Duret, Heubner). One artery, which very frequently gives way, passes from the middle cerebral through the anterior perforated spot, outwards between the island of Reil and the lenticular nucleus, the outer part of which it perforates, and then passes through the white 'internal capsule,' between the lenticular and caudate nuclei, to ramify in the anterior part of the latter. The arterioles supplying the convolutions on the surface of the brain are not often ruptured, except from injury. They are exposed much less directly to the blood-pressure, and sometimes possess considerable anastomoses.

SYMPTOMS.—The consequence of rupture of an artery is cerebral hemorrhage, the symptoms and treatment of which are described elsewhere (see BRAIN, Hemorrhage into). In traumatic laceration of the brain the arteries are torn, and often cause much hemorrhage.

(b) *Of Capillaries.*—The minutest arteries and veins and the capillaries rarely rupture, except when exposed to sudden pressure by venous thrombosis, when the obstruction in the part from which the vein proceeds may determine numerous capillary hemorrhages into the cerebral substance. In general venous congestion, as in asphyxial states, such hemorrhage may occur; but a more frequent result is rupture of a vessel within its perivascular sheath, which thus becomes distended with blood.

For SYMPTOMS see BRAIN, Hemorrhage into.

5. Syphilitic Disease.—The arteries of the brain are occasionally diseased in the later stages of syphilis. The large arteries at the base and the minute arterioles may be both involved. The wall is thickened at circumscribed areas by a fibro-nuclear growth, which causes a nodular projection on the exterior, and diminishes also the calibre of the vessel. The structure of the growth resembles that of syphilomata elsewhere. It is said by Heubner to begin by a nuclear proliferation between the inner coat and the elastic lamina; and in some cases it attains its chief development in this situation, the elastic lamina being pushed outwards and the lumen of the vessel obliterated. The middle coat may ultimately disappear. Vessels may form in the substance of the growth, and its centre may undergo fatty degeneration. The disease is sometimes sym-

metrical on the arteries of the two sides. The growth or secondary thrombosis occluding the vessel, softening may result in the area of brain-tissue supplied by it. The softening resembles in its occurrence and characters that which is produced by degenerative changes in the arteries, but is more varied in its seat, and it affects younger persons. The diminished elasticity of the diseased wall, when the thickening is slight, may permit the dilatation of the vessel into an aneurism. Possibly the same result may follow the fatty degeneration of the new tissue.

SYMPTOMS.—No symptoms are produced by the arterial disease until it causes local anæmia or softening, the symptoms of which resemble those due to other causes.

TREATMENT.—This is that of the later stages of syphilis. It must be remembered that the removal of arterial disease may not restore the damaged cerebral tissue.

6. **Thrombosis.** Thrombosis,—the coagulation of the blood *in situ*,—may occur in the cerebral arteries; or in the cerebral veins and sinuses.

(a) *In the Arteries.*

ÆTIOLOGY.—The causes of arterial thrombosis are the following:—

(1) An alteration in the wall of the artery, by which the blood comes in contact with an abnormal surface. The most common condition is atheroma, and hence arterial thrombosis is most frequent when atheroma is most common—in the old. Syphilitic disease of the artery sometimes leads to it. Much more rarely it is caused by an arteritis, spontaneous, or the result of adjacent inflammation or traumatic damage.

(2) Retardation of the blood-current. This may result from weakened action of the heart in debilitating diseases (as phthisis and cancer), and in extreme fatigue. It may be part of the effect of a convulsive fit; or it may be caused locally by the arterial diseases mentioned already, which lead to narrowing and loss of elasticity.

(3) An increased tendency of the blood to coagulate. This is seen in many diseases, especially in malarial states in young and old (such as are caused by phthisis and cancer), in acute rheumatism, and in the puerperal condition. A slight cause then suffices to produce coagulation, and the weak heart, so common in many of these conditions, may cause sufficient retardation of the blood-current.

(4) Lastly, thrombosis in an artery may be secondary to its complete or partial obstruction by an embolus.

ANATOMICAL CHARACTERS.—The arteries occluded may be one or several, and large or small. Of large arteries the basilar, middle cerebral, and carotid are those occluded most commonly, and with nearly equal frequency. The vascular wall may present any of the local causative conditions, or may be healthy. After a time thickening from secondary arteritis occurs. Within this vessel is a coagulum which usually fills its interior, and is adherent to the wall. It may not fill the vessel, either because originally imperfect, or because the clot has shrunk. A recent quickly-formed coagulum is red, but after a time it becomes pale and yellow. A slowly-formed coagulum is pale, and may be

laminated. A secondary clot usually forms far into the contracted distal branches, and on the proximal side as far as the nearest large branch. Ultimately the clot may, rarely, soften, the channel being sometimes re-established. More commonly it undergoes calcification, or, with the artery, contracts and becomes atrophied. The brain-tissue, in which the artery was distributed, may be at first anæmic, but quickly becomes congested. It ultimately undergoes softening—red, yellow, or white, according to the amount of vascular distension. If the collateral circulation is free it may remain unsoftened.

SYMPTOMS.—Where chronic arterial disease is the cause of thrombosis, the symptoms of local cerebral anæmia may precede (*see* BRAIN, Anæmia of). The thrombosis itself leads to the symptoms of loss of function in the part to which the artery passed. The onset of these symptoms is slow or sudden, according to the rapidity with which the coagulum forms; and their degree depends on the size of the vessel occluded, its position, and its relation to other vessels which may supply blood to the area involved. Thrombosis of a small vessel in the cerebral substance usually leads to transient brain-disturbance, headache, vertigo, tingling, and temporary weakness in the limbs, which soon pass away if a collateral circulation is established; more slowly, if softening ensues, by compensatory action elsewhere. The occlusion of a large vessel causes commonly more marked symptoms. Complete hemiplegia is frequent, and its onset may be marked by loss of consciousness (*see* BRAIN, Softening of).

DIAGNOSIS.—Diagnosis rests on a combination of the symptoms of local cerebral disease with the causal condition—vascular mischief (indicated by probable age, degeneration elsewhere, or syphilis), and with conditions leading to relaxation of the blood-current, or increased coagulability of the blood. The diagnosis is rendered more probable by the symptoms if slight being transient, if severe being of gradual onset, and, whether slight or severe, being preceded by the premonitory indications of local cerebral anæmia.

The PROGNOSIS and TREATMENT of thrombosis in arteries are considered under its consequence, BRAIN, Softening of.

(b) *In Cerebral Veins and Sinuses.*

ÆTIOLOGY.—Thrombosis in sinuses may be primary, and due to changes in the constitution or the circulation of the blood; or secondary, and due to local causes inducing coagulation directly at the spot affected. The same conditions of retarded circulation and altered blood-state which permit coagulation in arteries, favour it also in veins, and it is often seen in such conditions as phthisis and cancer, and especially in malarial states in children. Local retardation of the circulation from narrowing of the sinus, or compression of the jugular vein, occasionally assists. Local change causing coagulation is usually the extension to the sinus of adjacent inflammation, or of a clot produced in a tributary vein by such inflammation. Caries of the base of the skull, especially of the temporal bone, and meningitis are common causes. Inflammation outside the skull, in the scalp, neck, or face, has

led, by means of venous connections, to intracranial thrombosis. Lastly, injuries of the skull involving the sinuses sometimes cause coagulation in them.

ANATOMICAL CHARACTERS.—Of primary thrombosis the superior longitudinal sinus is the most common seat, and thence the clot spreads into the veins on either side, and often also into the lateral sinuses. When secondary, the thrombosis occurs in the sinus nearest to the local mischief; in disease of the petrous lobe, the lateral sinus is usually involved. The sinus is distended by firm clot, commonly (not invariably) adherent, sometimes in concentric layers. The walls of the vessel are healthy when the thrombosis is primary or secondary by extension of clot, but thickened and brittle when invaded directly by violent inflammation. After a time the clot may soften and break down.

The consequence of venous thrombosis is local arrest of the blood-current, the tributary veins and capillaries becoming enormously distended with blood and rupturing, and the cerebral substance being crammed with minute capillary extravasations which often coalesce. The condition is frequently seen in the convolutions. Blood is also effused into the meshes of the pia mater, and into the subarachnoid space. Into the looser tissues and into the ventricles serum may escape. Thrombosis of the veins of Galen is one cause of ventricular effusion. Ultimately the brain-tissue, the seat of the ischemic congestion, undergoes softening, first red, and then yellow or white. Occasionally the softening of the clot leads to pyæmia.

SYMPTOMS.—The symptoms are at first those of mental excitement, namely, intense headache and muscular spasm, shown as contractions in the limbs, or as convulsion, often beginning locally, according to the position of the congestion. These symptoms, after one or several days, are succeeded by those of depression; with coma, and dilatation of pupils. The coma may come on suddenly, and the first stage may be little marked. Convulsions, when present, often continue till death. When the superior longitudinal sinus is plugged, epistaxis, œdema of the forehead, and exophthalmos have sometimes been observed. When the lateral sinus is obstructed, there may be painful œdema behind the ear, and the jugular vein on that side has been noticed to be less full than on the other.

DIAGNOSIS.—The diagnosis rests on the occurrence of severe cerebral symptoms in association with a casual condition, constitutional or local.

PROGNOSIS.—This is always serious, death being, in most cases, speedy.

TREATMENT.—The indications for treatment are mostly causal. In primary thrombosis stimulants and nutritious diet are necessary, and tonic if they can be taken. In secondary thrombosis, occurring in robust individuals, leeching or cupping is recommended; purgatives should be given; and, in the less severe cases, a blister may be applied to the neck, and the utmost care taken to afford free exit for pent-up inflammatory products. Pain and convulsion are relieved most effectually by cold to the head.

W. R. GOWEN.

BRAIN-FEVER. A name popularly applied to any kind of febrile state in which symptoms of cerebral excitement are prominent; as well as to cases of inflammatory disease of the brain or its membranes.

BREAK-BONE FEVER. A synonym for Dengue. See DENGUE.

BREAST, Diseases of.—This subject will be treated under the following divisions:—

I. *Diseases before puberty*, in both sexes. II. *Diseases about the age of the establishment of puberty; and after that period*, in the female. (A), in the active state of the gland, (B), in the passive state. III. *Diseases affecting the rudimentary organ in the male*. IV. *Diseases of the nipple*.

The diseases of an organ composed essentially of glandular structures have here to be described. The mammary gland is classed with those termed racemose, but it differs from every other organ in the body of a similar class, inasmuch as it only arrives at maturity when its function is to be subservient to the nourishment of the offspring. In its perfection it appears, normally, only in the female sex, and even then it does not become developed until the internal organs of generation are capable of performing their functions.

Hence, to describe systematically the diseases of the breast, it is requisite to treat of them not only in reference to sex, but also in relation to the different periods of life at which certain diseases appear. Briefly then, from a histological point of view, they occur: (a) in the rudimentary state of the gland; (b) in its mature state; (c) when it has become a secreting organ, (d) during a state of degeneration.

I. In the *rudimentary period* of the gland the tissues composing it are rarely liable to morbid derangement. Usually, soon after birth especially in male infants, the rudimentary nipple and the skin of the region within the zone of the areola become slightly elevated and of a pink hue. In some infants a secretion, slightly milk-like, oozes from the ducts. In this state, the injudicious rubbing practised by the attendant excites inflammation, which, if not arrested by desistance from that pernicious interference, may advance to suppuration. When that happens, the usual local application of warmth and moisture suffices to give relief.

II. *About that age, in both sexes*, when the development of the generative organs advances with greater rapidity to maturity than in early life, the breast-gland enlarges, and may be painful, thus causing anxiety to the individual. Usually, symmetrical development takes place in the female; but, when the gland of one side takes precedence of that on the other, the circumstance need only be regarded as a departure from the ordinary rule, for no trouble will result, and in due time both will attain their normal proportions. In the male, pain or uneasiness sometimes occurs for a few days about this period, very often excited by the pressure of the dress. The removal of this cause is sufficient to arrest further mischief.

In the female the development of the breast having reached maturity, the gland is now asso-

diated by sympathetic influences communicated through nervous stimuli with the functions of the pelvic generative organs. This physiological fact should ever be remembered when investigating the nature of the morbid affections of this organ.

In a clinical point of view, it is essential to examine the diseases of the breast under the two states before mentioned, namely, (A) whilst the gland is undergoing metamorphosis into a secreting organ, and during lactation. (B) As a mature gland, but passive as regards its function.

Glancing at the various morbid states of the body of the gland as a whole, they may be divided, primarily, into two groups:—the *Functional* derangements; and the *Organic* or histological diseases.

We will now proceed to discuss these affections, as they are presented at the different periods mentioned above.

A. After conception the breasts soon begin to enlarge, and at their borders and surface minute pisiform indurations may be felt. Occasionally, but very rarely, this normal increase in bulk is attended with considerable pain and irritation extending throughout the nervous relations of the gland. The pain is referred to the back, neck, inside of arms, shoulders, and side of thorax, over, in fact, the area of distribution of those filaments which pass off to the skin from the same dorsal branches of the spinal nerves, the intercostals which send filaments to the breasts. It affords a good example of reflected irritation. This state usually occurs after the first conception, and in women of excitable, nervous temperament. Attention to ordinary hygienic measures during the progress of the metamorphosis of the organ into a secreting gland, with its accomplishment, affords relief to the pain. In large, lax, pendulous breasts, the separate lobes of which each is composed may excite apprehension of the existence of a tumour. But tumours composed of new tissue are so extremely rarely developed during pregnancy, that the greatest caution must be exercised in the diagnosis of their nature.

Very rarely, no change whatever in the breasts accompanies pregnancy, under which circumstances there is an absence of the secretion of milk after parturition—*Agalactia*.

Inflammation of the Breast.—*Mastitis*.

ÆTIOLOGY.—Before lactation, inflammation of the breasts is very uncommon. Afterwards, on the contrary, it is very frequent. This morbid state is often the result of carelessness or ignorance on the part of the nurse. The slightest unusual fulness or 'knottiness' discovered after the infant has been sucking, and when the ducts and their terminal secreting vesicles should be empty, requires immediate attention. Congestion of a lobule or lobe with milk produces the nodule, and the cause of the impediment to its escape should be sought for. The state of the nipple is generally the cause of the difficulty. Either the orifice of a duct may be obstructed by epithelium, or a superficial ulceration around one exists. The morbid or defective states of the nipple are the most fruitful causes of inflammation and its results in the breast. Prophylactic measures should always be instituted

when there is reason to fear that a defective development of the nipple will interfere with the free flow of the milk. Even with some mothers it would be advisable to resign the duty of suckling, rather than subject themselves to the almost certain misery arising from persistent and ineffectual attempts to do so. Inflammation, generally passing on to suppuration and abscess, either within the body of the breast or on its surface, is most frequent in primipara, and within the first month after parturition.

SYMPTOMS.—First, hardness is felt, 'a knot,' in some part of the substance of the organ; this enlarges, and may attain to considerable dimensions before causing pain or even uneasiness. Next, pain is felt during suckling; this increases each time the infant sucks, and 'the draught' is produced. The integuments then become pink, and afterwards red, tense, shining; more or less of the breast feeling very inelastic, firm, prominent, and heavy. Pain is now often very severe, and great constitutional disturbance is excited. In the centre of the redness the skin becomes of a purplish tint, around this it is oedematous, and with the finger, at the centre of the purple zone, a slight depression and softening spot can be detected. An abscess now exists, and in proportion to the quantity of pus fluctuation is more or less marked. At the purple centre the cuticle has probably by this time separated from the cutis, and a vesicle containing serum, either yellow or slightly tinged with blood, indicates that ulceration of the cutis is proceeding, and that the pus will soon escape. The above is a brief description of the objective signs indicating the morbid processes noticeable in all cases of local inflammation advancing to and terminating in suppuration and abscess. It is not possible to state with any degree of exactness the period of time required for the accomplishment of these definite changes. It varies according to so many local and constitutional circumstances, that it would be idle to attempt to predict any certain definite period or stage for each phase. It will be more useful to describe the treatment by which the progress of the disease may be arrested or limited and its painful course mitigated.

TREATMENT.—Great attention should always be given to the nipple of primipara. In many women, this important division of the gland is very small and undeveloped, perhaps only on one side, so that the infant, especially if not very strong, has great difficulty in obtaining sufficient milk to appease the appetite, and its efforts cause pain in the part. This circumstance induces the mother to prefer suckling most with that breast the nipple of which is perfect, and the infant soon appreciates the advantages of that side. Consequently the gland-tissue of that breast having the imperfect nipple becomes congested. Every time the infant sucks it becomes worse, more and more pain and irritation are excited, the orifices of one or more of the ducts in the nipple become blocked, and perhaps the infant refuses to suck the breast. But the gland becomes more and more distended, the nipple deeply buried, until at last suckling is impracticable. Probably none of these increasing troubles have been stated to the attending surgeon; and, when he is consulted, he finds the

breast to be in the state above described. The perfect development of the nipple should be always a subject of anxious solicitude on the part of the obstetric practitioner. If that organ be imperfect, precautions should be taken to prevent the gland itself from becoming congested, and if the infant cannot draw the milk sufficiently, some mechanical means should be employed to effect this object. The nipple itself should be carefully examined. If its end be more than usually coated with a white secretion, or the openings of the ducts seem to be obstructed with an excess of epithelium, attempts may be made to remove it. If minute abrasions, ulcers, 'cracks or chaps,' are visible between the rugæ, some soothing application should be used. Frequent ablation with warm water, even the contact of a little moist cotton fibre covered with tissue gutta-percha, is very preferable to the dry dress; or, if there be much secretion from the glands on the nipple, after cleansing its surface, some dry powder, such as carbonate of magnesia, oxide of zinc, or starch powder is beneficial.

When actual congestion of the gland-tissue exists, mechanical means should be used to reduce it. Supporting the gland with strips of plaster and a bandage is sometimes very useful. When inflammation is excited, local applications of warmth and moisture are indicated, and the constitutional condition of the sufferer demands special attention. When suppuration has taken place, its relation to the adjacent parts and the exact site of the abscess when formed should be carefully examined. Great diversity in the progress, duration, and sufferings of the patient depends upon the locality of the pus. It may be situated over the body of the gland, within it, and beneath it. When overlying or superficial to the body of the breast, the course of the disease is rapid, the pus soon points and escapes, and the wound heals. In those cases the constitutional disturbance is usually trifling. Water-dressing before and after the escape of the pus is preferable to the heavy poultices usually employed. The entire organ may be supported with strips of adhesive plaster and a bandage during cicatrization. But a bandage dexterously applied should be always used.

Both the local and constitutional symptoms are much more severe when inflammation affects the body of the gland, and pus collects between its lobes. The progress of the disease is tedious, pointing of the pus slow, and the exact spot at which it may reach the surface is for a long time doubtful. In the majority of cases it makes its way between the ducts and reaches the surface near the areola or within its area; usually to the sternal side of the nipple, where the gland tissue is thinnest. The surgeon should note this fact, for as soon as he can detect a softening of the cutis, by ulceration, he may, with advantage, make an incision at that spot, and thus give immediate relief by facilitating the escape of the pus. In these cases recurrent abscesses are not uncommon, and therefore the incision should be free, and its premature closure by adhesion must be avoided. All incisions should be made in a line parallel to the course of the ducts, never transversely to their axis. Manual pressure to hasten the escape of the pus is not admissible,

the natural contractility of the tissues being quite sufficient for the purpose.

When the abscess forms behind the breast the local appearances are quite characteristic. The gland itself seems little involved, but it is pushed prominently forwards and seems to repose upon a cushion of fluid. To the touch the elasticity of the swelling is very striking, and, without producing additional pain, a slight bulging of the walls of the abscess may sometimes be produced at the periphery of the gland when, with the palm of the hand and outspread fingers, compression is made from the front backwards against the thorax. The patient should be recumbent. The pus in these cases often points somewhere around the borders of the body of the gland.

During the time occupied in the formation of a mammary abscess and its local treatment, the constitutional powers of the patient must be well supported, and the general health maintained by every means.

The *sequelæ* of suppuration in an organ composed of so much connective-tissue, and endowed with its peculiar function, frequently cause great trouble. They are protracted induration, sinuses, and fistulæ, through which last the milk persistently escapes. Induration of the whole or part of the breast subsides when lactation ceases, and the organ in due time resumes its healthy state. Sinuses and fistulæ may require incisions, but the ordinary plan for their cure should be adopted before having recourse to a treatment often involving much subsequent deformity.

At the time for weaning the infant inflammation rarely occurs. Considerable milk-congestion of the secreting structure may sometimes produce irritation and inconvenience, to be relieved by mechanically drawing the milk in just sufficient quantity only to diminish the fulness.

Galacticoele.—An accumulation of milk, to which the above term is given, forms a tumour in the connective-tissue of the organ, and results from the bursting of a lactiferous tube. The swelling always appears first during lactation. It may vary in size from time to time; sometimes enlarging rapidly as suckling goes on. Two varieties are met with. In one form there is a single swelling near the nipple, quite superficial, and quickly recognizable by its objective signs. In the other there may be several swellings distinguishable in the substance of the gland, as well as on its surface, all of comparatively small size, very firm and globular. In the same gland they vary very much in size, and in the degree of resistance they offer to manipulation. The discrimination between these tumours and others in the breast is easy, if the surgeon is able to ascertain with exactness that the swelling appeared somewhat suddenly during suckling, and that its size varied conformably with that function.

In cases of long standing, the contents of the cyst become solid in proportion to the quantity of the fluid constituents of the milk absorbed, and the cyst wall itself is very often rigid and even may become gritty.

TREATMENT.—The treatment of this malady consists in cutting into the cyst, removing its contents, and allowing the wound to heal by granulation.

B. The diseases affecting the mature gland, in its *passive* state, from the age of puberty to that period of life when the catamenia cease, may be grouped as follows:—the *functional* affections, or those which are characterised by changes in the secreting portion of the gland, accompanied by more or less induration, inconvenience, and pain; the *organic*, or those diseases characterised by some new-growth, formation, or tissue-structure altogether a superaddition to the organ, and growing within its sphere of nutrition, often resembling, more or less, gland-structure in composition; and others the minute elements of which are nucleated cells of various shapes, definitely and diversely arranged.

In this state of the breast *inflammation* rarely occurs. Nevertheless, both the acute and chronic varieties of that morbid process terminating in abscess are met with, and careful discrimination is necessary to avoid mistaking such diseases for tissue-tumours, especially in patients above forty years old. The history of the case, tactile examination, and the variations occurring during the progress of the affection, commonly suffice for the detection of such cases. The treatment should be the same as for abscess in general.

Functional Derangements.—The functional derangements of the breast in its passive state demand special attention. They are characterised by a peculiar activity of its secreting portion, which undergoes structural changes of a specific kind. When the tissues composing a mature gland, but perfectly passive, are examined with a microscope, the caecal terminations of the ducts are scarcely perceptible, and little else than fibre-tissue is seen. Here and there, perhaps, caeci may be detected containing minute aggregations of epithelium. But when, under some sympathetic excitement, with derangement of the functions of the pelvic generative organs, the secreting cells of the gland become active and are distended with epithelium, they induce more or less enlargement of the breast. But of such affections there is this important fact to be noticed. The whole breast need not be necessarily involved. On the contrary, one lobe only may be excited, and when this occurs the existence of a tumour is declared. When, after excision, such enlarged lobes are carefully examined with the microscope, normal gland-tissue is seen, the caecal ends of the ducts are readily recognised, and their immediate association with the excretory ducts may be observed. The former are gorged with epithelium; and true gland-tissue, less its peculiar secretion, has been developed.

Symptoms.—Associated with this state of the tissues of the breast, the patient complains of pain, both locally and spread over a very wide area. To express as briefly as possible the superficial regions affected and over which pain is felt, the reader must be reminded of the distribution of the nerve-filaments of the lower cervical plexus, and of the dorsal from which the second, third, fourth, and fifth middle and anterior intercostal nerves pass off. From these, special filaments are distributed to the breast; and to the site of exit of one or more of them at the intercostal foramina, the course of the pain is referred by

the patient. The skin of the neck, shoulder, side of thorax, and inside of arm receives filaments from the same source. Hence an explanation of the widely-diffused pain.

It is of the first importance to discriminate between this state of the gland-tissue and substantial new growths, especially because the latter cannot be removed by natural processes, whilst the former most probably will be. The objective signs are the following:—to the touch the excited gland-tissue is nodular, irregular over its surface, much identified and mingled with the body of the organ. If the whole breast be large and relaxed, the tips of the fingers may be innervated between the borders of the indurated lobe and the lobes not affected. If the entire body of the gland be morbidly firm, it feels like a disc-shaped mass lying on the thorax, under the borders of which the fingers can be pressed. Occasionally, at one or more spots along the periphery of the gland irregular nodules are perceptible, projecting into the connective-tissue around them. When one lobe is affected, the shape of the induration corresponding with that of a lobe, namely, broad at the periphery and gradually narrowing towards the areola, may be detected. Pain as a subjective indication is of great assistance in the diagnosis of these cases; but the source and course of the pain must be carefully traced. Generally manipulation of the induration produces increased pain; occasionally touching the induration, even however gently, is intolerable, and persistence in or repetition of the act strongly opposed by the sufferer. Light pressure should be made over the intercostal foramina, both the middle and anterior, when the pain excited thereby will correspond with the nerve-filaments of the affected lobe. Usually, pressure along the upper dorsal spinous processes excites pain also. The morbid affections above described occur in single women, married but sterile females, and young widows, at ages between twenty years and forty. More or less disturbance of the catamenia co-exists, either in relation to the frequency or quantity of the discharge. The patient complains of languor, inability for bodily or mental exertion, and is desponding and often alarmed for the possible consequences of the affection suggested by sympathising friends. She becomes irritable, restless at night, loses appetite for food, as well as all desire for social enjoyments, and becomes highly susceptible and emotional.

Diagnosis.—An exact diagnosis of these histological changes may be made if the manipulator examines the organ methodically. He should, first, gently grasp the induration between the thumb and fingers, when it will be distinctly appreciable. Afterwards, placing the palmar surface of the fingers over the surface of the breast and gently pressing backwards against the thorax, the induration cannot be detected. Should there still remain any doubt on the subject, let the patient recline on her opposite side on a sofa, and in this posture, if there exists a substantial new-growth, the integument is usually elevated by it.

Treatment.—The treatment of these cases consists in attention to the general health. Every

hygienic direction should be enjoined, and such medicines administered as conduce to its improvement. Local soothing applications are usually futile, and, except in those cases of extreme pain, are not advisable, since it is desirable to avoid manipulation of the part, and the frequent recurrence of the patient's thoughts to it. Should the gland be heavy and pendulous, a suspensory bandage, as thin as possible, may be adjusted.

New Formations.—We shall next describe the diseases of the mature gland arising from the development of new formations—either of tissues constituting new-growths; or of conditions causing collections of fluid of distinct and specific kinds. All of these may be thus arranged in three groups:—first, the *fluid* tumours; second, the *solid*; and, third, those composed of both *solid and fluid*.

A. Cysts.—The *fluid tumours*, commonly termed *cystic*, consist of a membranous sac with its contents. Now, calling to mind the histological divisions of the breast, and dwelling on the structural differences between its parts, the secreting apparatus and the excretory, there is little difficulty in assigning to the cysts their true histological affinities. Thus there are cysts associated with the secreting apparatus, others with the excretory, the ducts; and some due to the extravasation of the gland's secretion, the milk, into the connective tissue. Effusions of blood also give rise to the development of cysts, either independently of other diseases or associated with them. Another variety of cyst is produced by the development of entozoa, notably of echinococcus hominis. An ordinary examination of the fluid derived from these cysts at once establishes the fact that heat and the admixture of nitric acid produce coagulation in that abstracted from some of them, whilst that from other cysts remains unaffected by the treatment. The cysts are thus divisible by the nature of their contents into two distinctly defined groups:—

a. Those containing fluid without the admixture of any coagulable element.

b. Those enclosing fluid which does contain coagulable material. Other characteristics of these two fluids are not less conspicuous.

From an objective point of view all cystic tumours of this gland may be classed in two groups, thus:—first, those associated with its ducts, the evidence of which is afforded by the escape of fluid at the nipple; and secondly, those not connected with the ducts by any such evidence.

The following tabular arrangement will place before the reader, at a glance, all the varieties of cysts met with in the breast.

I. Cysts associated with the ducts, communicating and connected with them.

1. Containing milk.

2. Enclosing growths; with serum, coagulable and often tinged with blood:—

a. Adenoid growths.

b. Granulation cell-growths.

c. Cancer.

Cysts not connected with the ducts.

1. Surrounding effused blood.

2. Enclosing milk.

3. Simple cysts.
4. Entozoon cysts. } Fluid not coagu-
lable.
5. Investing growths; with serum coagulable, tinged with blood and containing cholesterine:—
a. Adenoid growths.
b. Granulation cell-growths.
c. Cancer.

1. We have described above, under the name *galactiole*, a tumour observed during suckling and composed of milk. But, occasionally, the surgeon is consulted about a swelling which, at first sight, would seem to have no reference to that function. Nevertheless the milk, or all that remains of that secretion, constitutes its entire bulk. If exact enquiry be made, the patient states that a tumour has existed, unaccompanied by pain, from the period of the last weaning, perhaps not having been observed until the gland ceased to secrete, and that its size slowly diminished until a certain period, since which it has remained of unvarying bulk. This decrease is due to the absorption of the serum of the milk, and the solid parts remain. The cyst should be incised, the contents removed, and the wound allowed to heal by granulation.

Cysts containing the solid parts of the milk are sometimes associated with perfectly new growths of the glandular type.

2. True *sero-cysts*, that is to say, a collection of serum circumscribed by a fibrous membrane, are frequently met with, and are most commonly associated with adenoid, granulation, and cancerous growths. They occur in the breasts of middle-aged women. The fluid which these cysts contain is sometimes quite clear, and of a yellow tint; at others it is tinged with blood-colouring matter, and is turbid. It always contains some constituent coagulable by heat and the admixture of nitric acid. These are the exudation-cysts of the mammary gland. After the fluid has been removed with a trocar and canula the cyst soon refills.

3. Other cysts containing a fluid like serum, until its composition is carefully examined, are developed in the breast, and are probably associated immediately with the secreting part of the gland. For the sake of identification the writer would designate them *mucous cysts*. The contained fluid is not coagulable by either heat or acid. Its colour is brown, more or less inclining to a greenish hue; it is opalescent, of variable specific gravity—about 1020, rather greasy when rubbed between the fingers, and exhibits an alkaline reaction. When sufficient quantity is collected in a test-tube and allowed to cool, in a few hours the lowermost stratum of the fluid becomes clearer than the upper. The uppermost always remains opalescent. If a little of this last be examined with a microscope, oil globules are seen, together with the bodies called colostrum cells. The greasy nature of the fluid can be detected by smearing a drop of it on a piece of glass.

The development of these cysts is not very common. We may here remark that they seem to have escaped the observation of surgeons, as no special notice of them occurs in the most recent monographs. Yet they are so distinctly separated from all the other cysts which are

formed in the breast, in respect of the composition of their fluid contents, their progress, and their prognosis, that they constitute a marked, distinct, and isolated class. We meet with them in the breasts of single women, in married but sterile females, and in widows between forty and fifty years of age. Usually they are accidentally discovered in any quarter of the gland when about an inch in diameter. Their shape is globular, or ovoid, to the touch elasticity is the main feature, and if sufficiently large and superficial, fluctuation may be detected. In some instances the tips of the fingers may be insinuated into a sort of furrow around them. Pain is rarely complained of. The treatment consists in emptying the cyst with a trocar and canula. After this the fluid does not again form. These cysts usually appear singly and in one breast only, but the writer has seen a patient in whom they were multiple and on both sides.

4. Cysts containing blood—*hematomata*, are very rarely formed in the breast, except in association with some new-growth from which blood, or more often bloody serum, oozes.

5. True *entocou-cysts* are developed in the breast. They are certainly rare, and cannot be distinguished from other cysts until incised. Extirpation by excision is the speediest means of effecting a cure.

B. Solid Tumours.—We have next to describe the solid tumours. These are essentially new growths of tissue superadded to the normal gland. Generally, therefore, a characteristic feature of the existence of such growths is an increased bulk of the affected organ; another, the firmness or resistance to pressure with the fingers when contrasted with the group of tumours before described. The solid tumours have long been classed in regard to their local and constitutional effects, and their results on the life of the individual affected with them, into two groups—the *innocent* or harmless; and the *malignant* or life-destroying.

1. *Adenoma*.—In the first class are placed those growths more or less closely resembling in their tissues those composing the glandular structure of the breast. Various terms have been assigned to these tumours, namely, Chronic mammary tumours, Pancreatic Sarcoma, Tumeur adénoïde, Corps fibreux, Hypertrophie partielle, Mammary glandular tumour, Fibroma, Adenocèle. Their composition is chiefly fibre-tissue, the cæci or acini of secreting structures, with more or less distinctly marked traces of ducts, being interspersed throughout the mass. The elementary nucleated cells are those of the gland and fibre-tissues.

Adenomata are developed in the breasts of young, unmarried women from the age of puberty upwards; rarely after thirty, but very commonly before that age. They may be intraglandular, occupying the substance or body of the gland, and having the normal gland-tissue investing them. In other instances they seem to be attached by a kind of pedicle either to its surface or margin. In every instance they are placed within the fascial investment of the organ. When attached, as just described, their remarkable mobility, slight lobulation of surface, and

firmness, coupled with the youth of the patient, are sufficient indications of the harmlessness of their nature. Usually they occur singly and in one breast; they may be multiple and in both breasts. The only means by which they can be removed is excision. However large the tumour, its removal should be always attempted without cutting away any portion of the normal breast. In most cases this can be done, especially if the patient be youthful and the growth of medium size, even should it be developed in the body of the gland and extend through it to the pectoral muscle. After thirty-five years of age it is expedient to remove the breast as well. Want of space precludes a lengthened histological description of these growths. It must suffice to state that a section shows a solid, uniform surface, divided into lobes and lobules by fibrous septa, sometimes slightly broken up by fissures or clefts in which there appears a little clear tenacious fluid. The growth is often very succulent, at other times only moist; its hue may be greyish, yellow or almost white. Its vascularity is scarcely perceptible. The prognosis of these cases is invariably favourable. In many instances excision is not necessary, and the surgeon must be guided in recommending an operation by the exigencies of the case specially under observation.

2. *Fatty tumour*.—Lipomata or masses of adipose tissue are developed in the breast, or rather in relation with it, to speak with accuracy. They are characterised by the usual indications, and require no special mention.

3. *Nævus*.—It may be questioned whether nævus, or a growth of true trabecular vascular fibre-tissue, is ever developed in the substance of the breast, that is to say, in the gland-tissue. The integument around the mamilla may certainly be so affected in early life before the development of the gland, and a subcutaneous nævus may exist at the site of the future organ; but to describe such a growth, in a girl of six years old, as a recent writer has done, as an example in which the whole organ was like a sponge and as large as half an orange, must be regarded as an error in pathology.

4. *Fibro-plastic*.—Under the term 'fibro-plastic' we include a group of new-growths composed of elementary nucleated cells of a fusiform or oval shape, disposed in a stroma of more or less fibre-tissue. They are developed in women of middle age, increase rapidly, and after excision are liable to grow again.

5. *Colloid*.—Colloid growths are very rarely met with in the breast. They appear in middle life, and are not distinguishable from other solid tumours until after excision.

6. *Carcinoma*.—Carcinoma, commonly called cancer, is developed in the breast in two distinct forms. The first, and most common, is that variety which is due to infiltration of the normal tissues of the gland by the elementary cells of cancer. It constitutes the *scirrhus* variety, the *carcinoma fibrosum* of the present day. The second is that kind which is produced by the development of a mass of true cancer-growths and is termed *tubercus*, often *medullary*. Varieties are met with in women after years of age, but the first much the most

quently. Previously to that age the disease is rare; from forty to fifty it is most commonly seen; and it becomes relatively less frequent as age advances. A larger number of married women are affected by it than single, and prolific women who have suckled their children are quite as prone to the disease as the sterile or those who have not suckled.

SYMPTOMS.—*Scirrhus* cancer commences in any region of the mammary gland, although most frequently perhaps in the axillary segment. A small, firm nodule is usually accidentally discovered, without the attention of the patient having been attracted to it by pain. Rarely, the whole organ is simultaneously infiltrated, but most frequently one lobe only is affected. The infiltration is often central in the body of the gland, especially when the organ is atrophied, and the reverse occurs when the extreme edge of a lobe is affected at its periphery. The infiltration may steadily increase until the whole breast forms a rigid, solid mass, but most frequently the larger part of the organ remains unaffected. The disease gives rise by its contraction to much deformity of the region, to dimpling, corrugation, and irregularities of the otherwise rotund integumental surface. The nipple, just in proportion to the effect of the growth upon the ducts, becomes retracted or drawn towards the tumour. Such are the ordinary objective signs of infiltrating cancer in its early stage. The progress made by the disease is subject to very remarkable variations in different individuals, and the stage above described may be long delayed. In some cases many months or even years may elapse before the growth assumes any grave importance. Sooner or later, however, the integument over the growth becomes adherent to it, infiltrated, and red, and advances towards ulceration. An ulcer now forms, the edges of which are everted, ragged, and attached to the growth beneath. A hole extending into the tumour becomes deeper and deeper; ichorous discharges, more or less profuse, continue without much pain; and the patient becomes at last worn-out, or succumbs to the ravages of a cancerous growth in a vital organ.

The *tuberculous* variety commences in a small circumscribed, globular nodule in the body of the gland; grows rapidly, separates the lobes of the organ; extends equally in all directions; and becomes adherent to the skin, which commonly sloughs and allows of a protruding, fungating mass.

In both varieties the axillary lymphatic glands sooner or later become involved in the disease, which may also spread to those in the neck and within the thorax.

TREATMENT.—Local applications exert little if any influence on the growth of cancer, but certainly those which reduce the local temperature are the best. The vital powers of the patient should be supported as much as possible by hygienic measures, and especially by ferruginous tonics. The removal of the primary growth before the contamination of the lymphatic system is of great importance, but whether by excision with a scalpel, or by means of escharotics, space will not admit of discussing. The writer inclines to the first method in the majority of cases.

C. Mixed Tumours.—To the group of mixed tumours belong:—1 Those composed of cysts, intracystic growths, and solid interspersed masses of new tissue. 2 *Granulation cysts*—cysts with growths attached to their walls, the elementary tissues of which resemble those of ordinary granulation-growths—whence the term applied to them. 3. Cysts, so-called, often formed upon the surface of cancers, in consequence of the slow exudation of serum from the growth itself.

1. Tumours of the first class belong pathologically to the group of adenoid formations, although they differ so remarkably in their external objective appearances, they are, when unalloyed with other growths, perfectly harmless. The sero-cystic disease of Brodie, and the proliferous cysts of Paget belong to this class.

2. The *granulation-cystic* growths constitute a class of themselves. It is only of late years that attention has been attracted to them. They are rarely met with, and when pure are unattended by untoward circumstances.

3. To the third class belongs a group of cases thoroughly cancerous in their nature, and differing only from the ordinary forms of that disease by the accidental formation of cysts. *See Tumours.*

III. Diseases of the Male Breast.—The male has sometimes a well-developed mammary gland, and the part is subject to the same diseases as the female. But the simple enlargement of the organ is harmless, and should not be interfered with. At the age of puberty the mammary region often becomes painful, owing in part to the pressure of the dress upon the mamma and the rudimentary organ. Inflammation followed by suppuration has been observed at this time.

IV. Diseases of the Nipple.—A *defective formation* of the nipple is of grave importance, and when it exists measures should be adopted to assist its elongation. This is to be done by using an exhausting glass, such as those employed to empty the gland of milk.

Inflammation and its effects produce much suffering, and at the period of suckling frequently excite deep-seated mischief. The small ulcers, called 'cracks,' 'chaps,' &c., which form between the rugæ on the apex and sides of the nipple, may be cured with an application of water-dressing, or by powdering the part with carbonate of magnesia or oxide of zinc, far more readily than with ointments.

Pendulous cutaneous growths occur on the nipple, and should be excised.

Cystic follicular tumours are sometimes seen within the zone of the areola. *See NIPPLE, Diseases of.*

JOHN BIRKBEY.

BREATH, The.—The expired air, or what is familiarly termed *the breath*, is important both from an ætiological and a clinical point of view, and the object of the present article is to present a brief summary of the main facts relating to this subject, with which, for practical purposes, it is necessary to be acquainted.

1. The ætiological relations of the breath will be more appropriately discussed under the general subject of ætiology (*see DISEASE, Causes of*), but a few of the more striking examples of the manner in which it affects the health may be

given here. It is well known that the expired air, if re-breathed by the same individual without having been purified by a proper admixture with atmospheric air, will produce serious effects upon the economy, and will ultimately lead to death by asphyxia. Again, the breath of a number of persons collected together in an ill-ventilated place may prove injurious to such individuals: the impure atmosphere thus generated tends to lower the general health, to retard the development of the young, to increase the virulence of infectious diseases, and to predispose to pulmonary affections. Indeed, some writers regard re-breathed air as one of the most prominent causes of pulmonary phthisis. Further, undoubtedly the expired air is a most important channel by which the poison of different infective diseases—for example, that of measles, scarlatina, or diphtheria—is conveyed from one individual to another. It has been affirmed that phthisis can be transmitted directly in this manner, but adequate proof of this statement is entirely wanting.

2. In a clinical point of view, the expired air may afford useful information in diagnosis; or it may present characters giving important indications for prognosis and treatment. It might be requisite in different cases to submit the breath to a more or less complete examination, and the following outline will serve to suggest the particulars to which attention should be directed in this examination, and to point out the practical uses which it may serve.

a. The breath has been made use of to distinguish between *real* and *apparent death*. For this purpose a delicate feather or a light is held before the mouth or nostrils, and it is noted whether either of these is disturbed; or a cold mirror is placed before the mouth, when, if breathing is going on, its surface will be clouded by the moisture condensed upon it. These tests are, however, not considered very reliable.

b. The *temperature* of the expired air may be important to notice. In some conditions it becomes exceedingly cold, and this may be readily perceptible to the hand, the breath having a chill feel, or it may be visible in consequence of the moisture in the expired air being condensed, even when the surrounding atmosphere is warm. This phenomenon is observed, for instance, in the collapse-stage of cholera. On the other hand, the temperature of the breath may be raised more or less, as in febrile diseases.

c. *Chemical examination* of the breath may prove of service, and it is probable that this might afford useful information, if it were resorted to more frequently than is the custom at present. In the first place this examination may be employed to determine the proportion of carbonic acid present. In certain affections, as during an attack of asthma, or in cases of extensive bronchitis, the amount of carbonic acid in the expired air is more or less increased; in others, such as in the collapse-stage of cholera, this ingredient may be very deficient. Again, chemical examination of the breath may reveal the presence of a poison in the system, introduced from without, for example, hydrocyanic acid. It has also been employed to show the existence of deleterious products generated within the body,

especially in cases of renal disease. It is affirmed that ammonia may be detected in the breath in some cases of this kind, by holding a glass rod dipped in hydrochloric acid before the mouth, the ammonia being a product of the decomposition of urea.

d. *Microscopic examination* of the expired air has been attempted, but at present no results of practical value have been obtained.

e. The *odour* of the breath is the most important character demanding attention in a practical point of view. It is easily recognised, and the practitioner should always be on the alert to notice the smell of the breath of a patient, as this often affords material aid in diagnosis, and may even reveal certain morbid conditions which otherwise are liable to be entirely overlooked. Besides, patients not uncommonly seek advice on account of 'foulness of breath,' as a symptom for which they require special treatment. The following summary will indicate the principal circumstances under which this clinical phenomenon may prove of service in diagnosis, and in the course of the remarks it will be pointed out in what conditions the breath is particularly offensive. At the outset it must be observed that in some individuals the breath seems to have naturally a more or less disagreeable odour, which cannot be referred to any particular cause, and this amounts occasionally to extreme foulness. In females this may only be noticed at certain periods, and in some instances it seems to pass off in course of time. Again, it must be borne in mind that the breath is frequently unpleasant, either temporarily or constantly, from persons eating certain articles of food, or indulging in certain habits, such as excessive smoking, chewing tobacco, &c.

(1) The odour of the expired air may aid in recognising poisons in the system. The smell of prussic acid or laudanum, for instance, may be revealed when either of these is present in the stomach. Alcohol, however, chiefly demands attention in this relationship. In cases of acute alcoholic poisoning, the odour of the alcohol or of its products is at once apparent; and in persons who are found in a state of unconsciousness, the cause of which is not known, the smell of the breath is made use of as one of the diagnostic signs of drunkenness, though it must be taken with great caution. It is in the chronic forms of alcoholism that the breath gives the most valuable information. In very marked cases of chronic alcoholism it has an intensely foul odour, which is quite characteristic; but it gives extremely important indications in less confirmed cases, where the other symptoms of alcoholism are not so apparent; and especially does it enable us to detect dram-drinkers, and to explain the symptoms of which they so frequently complain. These persons, if their habits are inquired into, generally give themselves an excellent character for temperance, and seem entirely to forget that those with whom they come into contact are endowed with organs of smell. Again, the breath may reveal the presence of certain metallic poisons in the system, of which mercury is the most important example, but lead may also affect its odour. The expired air is said to present the odour of ammonia in exceptional instances of uræmia,

due to the exhalation of carbonate of ammonia derived from the decomposition of urea.

(ii.) The breath has a peculiar, or more or less disagreeable odour, in connexion with several diseases. That which is associated with the febrile condition is well known. In various disorders of the digestive organs the breath is often very offensive, but it is not practicable to refer any particular odour to particular diseases of either of these organs; it may, however, be affirmed that an unpleasant smell is frequently associated with habitual constipation. In cases of stercoraceous vomiting the breath may have a fecal odour. In this relation it may be mentioned that in some cases of phthisis the writer has noticed a sickly smell of the breath which is quite characteristic, and which seems to depend upon the state of the stomach. In cases of cerebral diseases also, the breath often becomes exceedingly offensive, on account of the condition of the alimentary canal. Local morbid conditions about the mouth, throat, or nasal cavities constitute a most important class of affections which influence the odour of the breath, in many cases it becomes extremely foul, and may be quite peculiar in its characters. Among these conditions should be specially mentioned want of cleanliness of the mouth and teeth; decayed teeth; diseased bone in the mouth or nose; ulceration or gangrene about the mouth, especially cancrum oris, and gangrenous ulceration along the gums; suppuration, ulceration, or gangrene in the throat, either of local origin, or associated with syphilis, scarlatina, diphtheria, &c.; ulceration of the nasal mucous membrane, and chronic ozena; and malignant disease. The smell of the breath is of special value in drawing attention to some of these conditions, for they may exist without giving rise to any local symptoms whatever, and the patient may be quite unconscious that there is anything wrong. Several striking illustrations of this statement have come under the writer's observation. Again, certain conditions of the respiratory organs are liable to affect the odour of the expired air, and may render it unbearably fetid. Among these may be mentioned sloughing ulceration about the larynx, pulmonary gangrene in any form, and the decomposition of retained morbid products in dilated bronchial tubes, or in certain cavities. Here, again, the smell of the expired air may reveal what otherwise is liable to be entirely overlooked, and especially when the patient coughs, so as to expel some of the retained air out of the lungs. Lastly, the breath may have a peculiar odour in some special diseases, such as pyæmia and diabetes.

TREATMENT.—It is only intended here to offer a few remarks as to the treatment of *foulness of breath*. The first great indication is, of course, to seek out the cause of this symptom, and endeavour to remove or remedy this, by which in a large proportion of cases a cure may be readily effected. The habits should be duly regulated; the mouth and teeth properly cleansed; the alimentary canal maintained in good order and any special affection requiring treatment attended to. When unpleasant breath depends on the stomach, it may often be improved by taking charcoal powder or biscuits, at the same time

remedies being employed suitable for the particular affection present, and calculated to promote the functions of the alimentary canal, the bowels being also kept freely open. When the bad smell depends on local causes, it may be diminished by the use of antiseptic mouth-washes and gargles, such as solution of Condy's fluid, carbolic acid or creasote. Antiseptic inhalations are indicated when the respiratory organs are accountable for fætor of breath.

BRIGHT'S DISEASE.—The term *Bright's Disease* is now universally recognised as generic, and as including at least three different diseases of the kidney. Each of these maladies involves chiefly one of the individual structural elements of the organ, and only secondarily affects the others. There is thus a disease originating respectively in the uriniferous tubules, in the blood-vessels and particularly in the Malpighian tufts, and in the fibrous stroma. That which originates in the tubules is always inflammatory in its character, although the inflammation may be *acute* or *chronic*; that which commences in the vessels consists in a peculiar degenerative change, the so-called waxy, lardaceous, albuminoid, or amyloid degeneration, that which is proper to the stroma is an extremely chronic process, supposed by many to be inflammatory, but as it appears to others, rather of an hypertrophic character. In the following article are described:

- I. The *inflammatory affection*, affecting the tubules, or the stroma, or both.
- II. The *waxy or amyloid affection*, originating in the vessels.
- III. The *cirrhotic or gouty affection*, originating in the fibrous stroma.

DEFINITIONS.—I. *Inflammatory Bright's disease* is an acute or chronic affection of the kidneys; caused by exposure to cold, and by scarlatinal and other blood-poisons; consisting in inflammation of the elements, passing through various stages of transformation, viz. inflammatory enlargement, fatty degeneration, and atrophy; characterised in the earlier stages by diminution of urine, albuminuria, frequently hæmaturia, tube-casts, and crudit; in the later stages by the same symptoms, in a more or less marked degree, with secondary changes in the heart, blood-vessels, and other organs, terminating frequently in recovery in the early stage, rarely in the later, often in death by dropsy, uræmia, or intercurrent affections.

II. *Waxy Bright's disease* is a chronic affection of the kidney, caused by phthisis, syphilis, cancer, suppuration, and other exhausting conditions; consisting in waxy or amyloid degeneration of the Malpighian bodies, small arteries, and sometimes the basement membrane, with, in many cases, transudation into the tubules; passing through various stages of transformation, viz. simple degeneration enlargement from transudation, and atrophy; characterised by a large flow of albuminous urine of low specific gravity, and absence of dropsy; often attended by evidences of waxy disease of other organs, particularly the liver, spleen, and intestinal canal, resulting pro

bally in some cases in recovery, usually in death by exhaustion, uræmia, or coexisting affections of the kidneys and other organs.

III. *Cirrhotic Bright's disease* is a chronic affection of the kidney, caused generally by the abuse of alcohol, sometimes by the poison of gout, occasionally by plumbism, and by unknown conditions; consisting in increase of the fibrous stroma, with thickening of the capsule, and ultimate atrophy of the organ, characterised by a very insidious commencement, by the absence of the early symptoms of either of the other forms, by albuminuria, at first slight, but possibly absent, and by the ultimate appearance of enlargement of the heart, polyuria, albuminuric retinitis, œdema of the lungs, and uræmia; resulting ultimately in death from uræmia, œdema of the lungs, or other intercurrent affections.

ÆTIOLOGY.—I. Of the *inflammatory form*. Cold is the commonest cause in the adult. It acts especially on those who have been exposed to its influence whilst perspiring. It frequently contributes towards the production of the disease in persons otherwise predisposed. Various blood-diseases, while they induce temporary albuminuria along with their more ordinary symptoms, have renal inflammation as a common sequela. Among these scarlatina occupies the first place, diphtheria stands next in order, followed by erysipelas, measles, pyæmia, typhus, ague, acute rheumatism, and pneumonia. Many of these maladies being most common in childhood, it follows that in the earlier years of life they are the chief causes of inflammatory Bright's disease. Pregnancy, heart-disease, gout, and malaria contribute towards its production in some cases; and the undue use of cathartics, turpentine, or alcohol may also be reckoned as causes.

II. Of the *waxy form*. Constitutional syphilis, phthisis, prolonged suppuration, caries or necrosis of bone, and other exhausting diseases, such as cancer and chronic rheumatism, induce this degeneration. There is at present no satisfactory evidence as to the precise connexion between these influences and the morbid process.

III. Of the *cirrhotic form*. The commonest cause is the abuse of alcohol, particularly in the form of ardent spirits. After this, though at a long interval, rank gout and lead-poisoning. Congestion from cardiac disease is also by many authorities, but erroneously, held to be a cause. (See KIDNEYS, Congestion of.) As experience shows that the disease is often met with in people who have neither indulged in alcohol, been exposed to lead, nor suffered from gout, it is obvious that other efficient though yet undiscovered causes must exist.

ANATOMICAL CHARACTERS.—I. Of the *inflammatory form*. When a case of this kind is prolonged, the renal disease passes through several conditions, which, for convenience of description, may be divided into three stages. (a) *Stage of active inflammation*. In this stage the kidney is enlarged; its capsule strips off readily; its surface appears more or less red, sometimes of a deep purple colour; and occasionally extravasations of blood are present in its substance. On section the cortical substance is found to be

relatively increased in bulk. Its vessels, as well as those of the cones, are congested. The structure appears somewhat coarser than natural, while the convoluted tubules often present a swollen opaque appearance, and occasionally contain blood. On microscopic examination the congestion of the vessels becomes very apparent, and the tubules are found to be dark and opaque, their lumen being frequently occluded. The individual epithelial cells are granular, and in a state of cloudy swelling. In some cases almost all the tubules appear affected, in others comparatively few. The enlargement of the organ is in part due to congestion, in part to exudation into the tubules. As the exudation increases the congestion becomes less marked, so that in the later period of this stage the kidney appears paler and more opaque. Unless recovery or death takes place, this condition passes into (b) *The second stage, that of fatty transformation*. In this stage the organ is still enlarged. Its capsule strips off readily; the surface often presents stellate veins, and its colour is mottled. At this time extravasations are very rarely observed, but there are alternating patches of yellowish opaque sebaceous-looking material, mingled with more natural structure. On section the cortical substance is seen to be relatively increased. There is no congestion of the vessels, and the Malpighian bodies are not prominent. The convoluted tubules are in many parts occupied by the sebaceous-like material, and sometimes the straight tubules present the same appearance. On microscopic examination the tubules alone are found affected. Many of them present under low powers a black appearance, due to fatty degeneration of the contents of the tubules. It is in the cells alone that this change occurs, and not, so far as the writer has seen, in the free exudation which binds the cells together. Many of the tubules are completely blocked up by this material; and sometimes in making the section there is such an amount of oil set free, that it permeates the whole structure of the organ, and is liable to produce the impression that the fatty degeneration is universal. This condition may be developed within a week or two of the commencement of the inflammation, and it may continue for years. During the whole course of the second stage it must be understood that inflammatory action is going on, although much less acutely than at first, and less widely diffused. The disease is sometimes recovered from, and if the patient survive long enough it passes into (c) *The third stage, that of atrophy*. The organ is then reduced to or even below the natural size. Its capsule strips off with little difficulty, and without tearing the surface. The surface is uneven; it rarely appears coarsely granular, as in the cirrhotic form, but rather presents a series of depressions, which give it an uneven or finely granular character. Its colour is very similar to that described as occurring in the second stage, but there is less of the sebaceous-looking material. On section the cortical substance is found relatively diminished. The Malpighian bodies are not prominent. The tissue feels more dense; and many of the tubules are occupied by sebaceous-looking material. The blood-vessels;

and particularly the small arteries, are sclerosed: the intima and the adventitia are frequently, the middle coat almost invariably, thickened. The fibrous stroma is relatively increased, especially towards the surface of the organ, and the tubules may be traced in different stages of atrophy. On close inspection that atrophy is found to result not from pressure of the fibrous stroma, but from molecular absorption of the contents of the tubules. Besides the typical form of the inflammatory affection just described, notice should be taken of other varieties, such as the *glomerulo-nephritis* of Klebs, in which the glomeruli are especially affected. The anatomical changes met with in other organs are described along with the complications.

II. Of the *waxy or amyloid form*. This chronic morbid process may also, for convenience of description, be divided into three stages. Of these the first is, (a) *The stage of degeneration proper*, in which the organ presents an almost normal appearance. The size is natural, the capsule strips off readily, and the colour is not altered. On section all appears normal, excepting that the Malpighian tufts, without being congested, are prominent, and in certain lights may be seen even by the naked eye to present dim translucency characteristic of waxy degeneration. On applying a little aqueous solution of iodine, the Malpighian tufts and the small arteries assume a peculiar mahogany hue. On examination with the microscope, the stroma and tubules are found to be healthy, the vascular structures being alone affected. The affection is often first seen and is most distinct in the middle coat of the arteries, the swollen transverse fibres taking on the colour, and producing what has been described as the *ipecauanha-root* appearance. How long this condition may last without the tubules becoming affected it is impossible at present to say, for it has only been met with in patients who had died of one or other of the causal complications while the renal malady was still in an early stage. Sooner or later it passes, however into the condition most commonly met with, (b) *the second stage, that of degeneration with secondary changes in the tubules*. In this condition the organ is enlarged. Its capsule strips off readily, the surface is smooth and pale, presenting, in pure examples, little or no mottling. On section the cortical substance appears relatively increased, and looks much paler than the cones. The structure usually is denser than natural. The vessels appear prominent, and the Malpighian tufts resemble minute grains of boiled sago. On the addition of iodine the degenerated parts become characteristically coloured, and stand out prominently from the tubular tissue, which does not exhibit the characteristic reaction. On microscopic examination the vessels are found altered as in the earlier stage, but the change is more advanced. The stroma is normal, but many of the tubules are altered. Some are blocked up by a dimly translucent, wax-like material, which however does not assume the mahogany colour on the addition of iodine. The epithelium in many of the tubules presents a finely granular appearance, and occasionally is somewhat fatty, but the epithelium and the basement membrane very rarely present

the characteristic reaction. This change in the tubules is thus secondary to the degeneration proper, which is confined to the vessels, and these secondary changes consist in some alteration of the nutrition of the epithelium, with exudation or transudation of coagulable material into the lumen of the tubes. This condition may last for years, but should the patient live long enough it passes into (c) *the third stage, that of atrophy*. The organ is then below the normal size; the capsule strips off readily, the surface presents an uneven granular appearance, and is pale. On section the cortical substance is found relatively diminished. Its small arteries are prominent and thickened; its Malpighian bodies are very conspicuous, and are grouped together in consequence of the atrophy of the intervening structure. The stroma is relatively increased, and many of the tubules are destroyed, while of those which remain not a few present the characters above described as being met with in the second stage. The organ may, in extreme cases, be diminished to less than half its natural size.

III. Of the *cirrhotic form*. The course of this affection is even more chronic than that of the waxy form. It consists essentially in an increased growth of the fibrous stroma, with secondary changes in the tubules and vessels. In an early stage the organ may be found of fully the natural size. The capsule strips off less readily than in health. The surface is somewhat uneven, and may present cysts. On section the cortical substance is relatively enlarged, and this is due merely to an increase of the stroma, not to any change in the vessels or in the tubules. But it is in the more advanced stages that the disease is commonly seen. Then the organ is reduced in bulk, it may be slightly, it may be to one-fourth of its normal size. Its capsule cannot be peeled off without tearing the gland. The surface is uneven and granular, and often of a reddish colour. On section the cortical substance is found relatively diminished, its structure being dense and fibrous. The small arteries are thickened and very prominent, all their coats, but especially the middle, being increased in volume. Many of the tubules are atrophied, but the epithelium of such as are not involved is for the most part natural. Cysts are numerous, and are found in connexion with the tubules, the Malpighian bodies, and the cells.

There are two points worthy of being specially kept in view by those who desire to attain to clear conceptions of Bright's disease—viz. (1) That its different forms are very frequently combined—in particular that the inflammatory affection is found associated sometimes with the waxy disease, sometimes with the cirrhotic; but that the descriptions here given are derived from pure examples of each process; and (2) that atrophy results in all the forms if the disease lasts long enough; that is, that a small, uneven-surfaced kidney may result from either the inflammatory disease of the tubules, or the waxy disease of the vessels, as well as from the increased growth and subsequent contraction of the fibrous stroma in the cirrhotic form.

SYMPTOMS.—1. Of the *inflammatory form*. The leading clinical features of this variety, is

addition to the albuminuria which exists in all the forms of Bright's disease, are diminution in the quantity of urine, and the presence of dropsy.

The onset of the disease may be sudden or gradual. Sometimes it is the diminution and alteration of the urine that attracts attention, sometimes the dropsy, sometimes the gastric derangement and general uneasiness; but whichever symptom may appear first, the others usually speedily follow. The urine is generally diminished in quantity, often somewhat opaque, and smoky or even bloody. It contains much albumen and numerous tube-casts. The casts are granular, being composed mostly of epithelium in a state of cloudy swelling, sometimes bloody, frequently hyaline or fibrinous. The urea is diminished, it may be, to one-half one-fourth, or even a less proportion of the natural amount. This leads to a corresponding reduction of the specific gravity, unless there be a compensatory diminution of water, or increase of albumen. The dropsy is generally distinct in the face, and swelling of the eyelids is well marked in the morning. Towards evening, if the patient be out of bed, the legs are chiefly affected. The scrotum and penis are often swollen, and sometimes the abdomen is also dropsical. There is little quickening of pulse or elevation of temperature, but a good deal of general uneasiness is experienced, with debility and pain in the loins, and dyspeptic symptoms are often present, due to gastric catarrh. Such is the usual condition at the commencement of the disease, and during the period which has been already described as the first stage. But sometimes at this stage a much more serious condition is developed—namely, suppression of urine, followed by coma or convulsions leading to a fatal result; or dropsy may increase to such an extent as of itself to cause death. Or, again, without or even with the most unfavourable symptoms, under appropriate treatment the kidneys may begin to act more freely, the urine increasing in amount and improving in characters, with consequent gradual disappearance of the dropsy, and restoration of health. Or, as often happens, the general condition improves, but a chronic albuminuria remains, and the disease passes into the second stage. The urine is then no longer bloody, the quantity is greater, though still below the normal, the specific gravity is low, there is albumen, along with tube-casts, fatty, hyaline, or mixed partly fatty and partly hyaline. The urea is below the normal standard. The dropsy may continue, and may even gradually increase, or it may pass off and only appear when the patient is fatigued, or when he has caught cold. The general symptoms remain unchanged, except that anæmia comes on, and the patient's debility is suddenly increased. This course of events may pass on to a fatal result; or there may be complete, or, as is more common, merely partial recovery. In this condition the patient may linger for many months, occasionally suffering exacerbations, and he may succumb to one of them, or to one of the numerous complications to be presently described. If the patient passes into the third stage, he appears prematurely old. His urine is of natural amount or even somewhat increased in quantity, but of low specific gravity. It contains albumen

and a few casts, mostly hyaline, with scattered fatty cells imbedded in them. The urea is still diminished. There is dropsy of the feet and ankles in the evenings, and slight exposure brings on more general attacks. The face is pale and puffy, and the eyelids are often oedematous. The pulse becomes hard and tense; the arteries gradually become thickened from sclerosis and atheroma; while the apex-beat of the heart passes downwards to the left side owing to hypertrophy, particularly of the left ventricle. In this condition a fatal result may be induced by an acute exacerbation with general dropsy; by chronic, or more rarely, acute uræmia; or by intercurrent attacks of inflammatory or other affections of various organs.

2. *Of the waxy disease.* The onset of this affection is gradual and insidious. A patient who has suffered from phthisis, syphilis, or other wasting malady passes an excessive quantity of urine, and finds himself obliged to rise several times during the night for micturition. The urine is pale, of low specific gravity, containing at first no albumen, subsequently only a trace, ultimately a considerable amount. The urea is little, if at all, diminished; the tube-casts are extremely few, and mostly hyaline. There is no dropsy, but evidence of concomitant waxy affections of other organs is frequently afforded. The liver is enlarged, its margin being easily felt and sharply defined. The spleen is also increased in size. The blood is slightly altered, the white corpuscles being somewhat increased, and the red being rather flabby and ill-defined. These conditions gradually become more distinct, and the strength of the patient diminishes, partly from the disease of the kidneys and other organs, partly from the wasting diseases which have induced the degenerative changes. A case of the kind has been known to go on for nearly ten years, during which time the urine continued of the characters just described, and dropsy never appeared. At length the vital powers of the patient became depressed, head symptoms gradually supervened, and death ensued. It is not often that such an uncomplicated case is met with. More commonly the exhausting disease which led to the degeneration causes death before the waxy change has gone so far. Sometimes also intercurrent complications induce the fatal result. Clinical observation renders it probable that the kidneys, as well as the liver and spleen, may recover from their degeneration, in cases in which the causal malady has been got rid of.

3. *Of the uræmic disease.* The onset of this affection is extremely insidious, and it may exist for a long time without distinctly manifesting itself by symptoms. Its existence is often discovered only when dyspœnia, uræmic convulsions, or blindness from retinitis leads the patient to consult a medical man. The earliest symptoms are occasional slight albuminuria, and frequent calls to micturition during the night, the urine however not being excessive, its specific gravity being low, and the urea somewhat diminished. But when the disease has existed for some time the complexion becomes altered; the eye assumes a peculiar appearance, from oedema of the conjunctiva, the patient is subject to dyspeptic

attacks; the heart becomes hypertrophied, and the vessels sclerosed and degenerated; while there is little or no dropsy. When the disease is advanced, these changes in the circulatory organs are well-marked, and the cachectic condition becomes distinct. The occurrence of various complications, such as severe gastric catarrh, diarrhoea, anæmia, dyspnoea, bronchitis, œdema of the lungs, headache, uræmia, and the characteristic retinal affection, render the diagnosis easy. Frequently towards the end there is an increased flow of urine, of low specific gravity. This is in some cases a very prominent symptom. The disease is never recovered from, and the fatal result occurs from uræmia, from some inflammatory complication, such as pleurisy, pericarditis, bronchitis, or pneumonia, or from some result of degenerative change, as hæmorrhage from a mucous surface or into the brain.

COMPLICATIONS.—(a) Connected with the Abdomen and Alimentary System.

Gastric affections are met with in all the forms of Bright's disease. Catarrh of the stomach—acute, sub-acute, and chronic—is common to them all, and is characterised by an unusual tendency to nausea and vomiting. It is especially frequent during the first stage and in acute exacerbations of the inflammatory form, and is often a chief source of suffering during the most advanced stages. It is not uncommon during the whole course of the waxy form, but is most usually met with in the cirrhotic variety. So close indeed is the relationship between them, that in the management of cases of cirrhosis regard should constantly be had to the state of the stomach, and in no case of chronic gastric catarrh should the physician neglect to enquire into the state of the urine. This affection, when complicating the early stage of the inflammatory form, often owes its origin to the same cause as the kidney-affection is due to. When complicating the later stages of the inflammatory, and any of the stages of the cirrhotic disease, the catarrh is probably a result of efforts at elimination of materials retained in the blood by the failure of the action of the kidneys. When occurring in the waxy form, it is frequently due in part to the existence of waxy degeneration of the vessels of the gastric mucous membrane. In the waxy disease we sometimes find blood mingled with the vomited matters, just as we find hæmorrhage occurring in other organs when this degeneration exists.

Catarrh of the intestine also occasionally occurs, sometimes producing an exhausting diarrhoea, especially in advanced inflammatory and cirrhotic cases; but it is along with the waxy disease that intestinal symptoms are most common. These are due to waxy degeneration, and consequent ulceration; or to ordinary tubercular disease of the intestine. Both of these affections induce diarrhoea, but there is evidence that not only may it thus occur, but that blood may also be discharged, although there be no ulceration recognisable by the naked eye.

Hepatic affections.—Functional derangements of the liver occur in the course of all the forms of Bright's disease. The chief organic changes are fatty degeneration, waxy degeneration, cirrhosis, and syphilitic affections. The first-named is not specially related to any of the forms.

The waxy degeneration and the syphilitic affections are of course commonly met with as accompaniments of the waxy disease; whilst cirrhosis attends upon the cirrhotic kidney.

Ascites is often seen as a manifestation of general dropsy in the inflammatory form of Bright's disease; and sometimes this is a prominent symptom in mixed forms, when waxy liver is associated with a waxy and slightly inflammatory condition of the kidneys.

Peritonitis is occasionally the cause of death in all the forms of Bright's disease. It may result from local affections, or from the state of the blood; and may be acute, severe, and therefore obvious, or so insidious as scarcely to attract attention.

(8) Complications connected with the Blood, or with the Lymphatic and Blood-glands.

The *spleen* is usually unaffected in cases of inflammatory Bright's disease except such as prove fatal in the earliest stage, and in which the spleen is affected in common with the kidney. In the waxy and cirrhotic forms corresponding lesions are frequent in this organ.

The *lymphatic glands* are rarely altered excepting in the waxy form, in which they are sometimes the subject of the waxy degeneration, sometimes of tubercular disease, or of strumous inflammation.

The *blood* itself is altered in its chemical composition. In the inflammatory form its density is diminished, the corpuscles and albumen being deficient, while the water is correspondingly increased. The quantity of urea is above the normal. In long-standing cases of waxy disease similar changes are found, and not unfrequently there is a slight numerical increase of the white corpuscles, and flabbiness of the red blood discs when the spleen is affected. In the cirrhotic form like alterations also occur.

Hæmorrhage is apt to occur in advanced stages, especially of the cirrhotic form. It may take place from the kidneys, or from the mucous membranes, particularly that of the nostrils. In the inflammatory affection hæmaturia is common in the early stage; in the waxy variety this symptom occasionally occurs, but rarely to a serious extent.

(7) Complications affecting the Circulatory system.

Hypertrophy of the heart is almost always present in cases of advanced cirrhotic disease, and also in the advanced stages of the inflammatory affection. One may trace in patients the gradual development of this hypertrophy, advancing *pari passu* with the progress of the renal affection. It is comparatively rare in the waxy form. *Hydropericardium* is met with in some cases, as a manifestation of general dropsy. *Pericarditis* occurs as an intercurrent affection in all the forms, but especially the inflammatory and the cirrhotic. It is apt to be overlooked, owing to the absence of local pain, or from the pain being referred to the abdomen. *Endocarditis* is also frequently associated with the various forms of Bright's disease.

The *arteries* are sclerosed and atheromatous in the advanced stages of the inflammatory and in the cirrhotic, but not so much in the waxy disease. In that affection the small vessels in

where parts are frequently the seat of waxy degeneration. Thickening of the arteries occurs constantly in the more advanced stages of the inflammatory and cirrhotic diseases, and is due in great part to hypertrophy of their middle coat, in lesser degree to sclerosis of the tunica intima, the tunica adventitia, and perhaps the perivascular lymphatic sheath. The pulse becomes tense and sustained in chronic cases, partly from the hypertrophy of the heart, partly from the changes in the capillaries and smaller arteries.

(3) Complications connected with the Respiratory system.

Acute bronchitis is common, especially in the advanced stages of Bright's disease, and tends to pass into the chronic state. Bronchitis may originate also as a sub-acute or chronic affection. *Edema of the lungs* is very common in advanced stages, and frequently occurs as a manifestation of general dropsy in the early, as well as in the later stages of Bright's disease. It may be very suddenly developed in cirrhotic cases, and may rapidly prove fatal. *Pneumonia* occurs sometimes as a cause of inflammatory Bright's disease, sometimes as a consequence of exposure to cold during the course of chronic cases. *Phthisis* in its various forms is found especially associated with these renal affections, frequently with the waxy, and more rarely with the inflammatory form. It usually proves fatal while the renal malady is yet in its early stage. *Hydrothorax*, acute or chronic, is often seen in dropsical cases. *Pleurisy* occasionally occurs with all the forms of Bright's disease, and may be due to the state of the blood; or, as seems more likely, to increased susceptibility to inflammatory changes, which results from the lowered vitality of the organism. *Dyspnea* is frequently met with in the inflammatory and cirrhotic forms of the disease, and may be independent of any local lesion, being probably a result of uræmic poisoning. *Edema glottidis* is apt to occur in inflammatory cases, when even a slight laryngitis has from any cause been brought on.

(c) Complications affecting the Skin and Subcutaneous tissues.

Dropsy, in the form of anasarca, is almost constantly present in the early stage, and during exacerbations of the inflammatory form. It can scarcely be said to occur in uncomplicated waxy and cirrhotic cases. *Eczema* is occasionally troublesome in chronic cases. *Erysipelas* is met with now and then always constituting a serious addition to the other malady.

(5) Complications affecting the Urinary organs.

The chief of these is scrofulous disease of the kidney, and more rarely of the bladder and prostate. They occasionally occur along with the waxy affection.

(n) Complications affecting the Nervous system and Special senses.

Uræmic blindness may occur, which is sudden and usually temporary, being unaccompanied by any lesion recognisable by the ophthalmoscope. It is generally met with in advanced cirrhotic and inflammatory cases. *Retinitis albuminurica* is a peculiar and characteristic inflammation of the connective tissue of the retina, leading to the formation of white patches and lines, with

fatty degeneration. With it are also frequently associated minute hæmorrhages into the substance of the retina. This occurs by far the most frequently in cirrhosis. It is often also seen in the advanced stages of the inflammatory form, and is rarely recovered from except in the case of pregnant women, in whom it seems apt to occur as a passing condition.

Uræmia includes a group of the most striking symptoms of Bright's disease. It may occur at the commencement of the acute inflammatory affection, or in its later stages, or in the chronic forms. The condition is, however, rare in the purely waxy disease, but common in the cirrhotic. There are several types of uræmia, of which the most important are:—(a) Sudden acute convulsions, followed by coma and death; (b) Gradually advancing torpor, passing at last into coma. The clinical features of these and minor varieties are described, and the hypotheses as to their origin discussed, in the article URÆMIA.

Headache is frequently complained of by patients suffering from Bright's disease. *Apoplexy* from hæmorrhage into the substance of the brain is common in the later stages of the inflammatory and cirrhotic diseases. It is due partly to the degenerated state of the vessels, and partly to the increased pressure resulting from cardiac hypertrophy.

(6) Complications affecting the Locomotory system.

Of these the only ones of importance are *disease of bone*, which has been already referred to as a causal complication in waxy cases; and *joint affections*, which have been mentioned in connexion with the cirrhotic disease.

DIAGNOSIS. (a) Of Bright's Disease from other affections. From passive congestion of the kidneys due to cardiac disease these maladies are distinguished by the general condition of the patient, the absence of uræmic disease, and of congestion in other organs; and the characters of the urine. In heart-affections the urine is generally scanty, high-coloured, not of low specific gravity. It may contain albumin, and deposits urates, but rarely blood, renal epithelium or tube-casts. Hyaline casts may be present, but never in any large quantity. The presence of epithelial and fatty casts, or marked diminution of the amount of urea in any case, proves at least the co-existence of actual inflammation of the kidney. From *paroxysmal hæmaturia* and *albuminuria*, Bright's diseases are distinguished by the abrupt commencement and brief duration of these maladies; by the marked nervous symptoms, with gastric catarrh, and sometimes slight purities; and by the absence of dropsy. In hæmaturia also the condition of the urine is very distinctive; the dark-red colour being due, not to blood-corpuscles, but to granular pigment, the deposit consisting mostly of this material and of hyaline casts. In *paroxysmal albuminuria* again the amount of albumin is very large, and the number of tube-casts extraordinary. *Hæmaturia*, with tendency to suppression of urine, is distinguished from Bright's disease by the small proportion of epithelial tube-casts, and in some cases by the complete absence of casts. There may be a question whether the case is one of hæmaturia or of commencing acute inflam-

matory Bright's disease; or again whether it is one of a chronic affection, cirrhotic or cystic, in which hemorrhage has come on. The cases in which Bright's disease simulates hæmaturia are generally the sequelæ of scarlatina or diphtheria; and, therefore, even when these diseases have been overlooked, the presence of desquamation or of paralysis may afford a clue; but the peculiar reddish-brown deposit rich in cells and in epithelial tube-casts, which occurs in Bright's disease, makes the case clearer even when, as often happens, there is no dropsy, or when, as we sometimes see, the albumen is not coagulated by heat or by nitric acid. Again, when the question is between simple hæmaturia and hæmaturia with cirrhosis or cystic disease, the evidence afforded by the tube-casts is not important, but the hypertrophy of the heart, the thickening of the arteries, the character of the pulse, the albuminuric retinitis, the low specific gravity of the urine and the small amount of urea which it contains, as well as the tendency to hæmorrhage from other sources, afford evidence of the presence of the chronic organic disease.

Slight *pyelitis*, with or without renal calculus or gravel, may simulate Bright's disease, but the history of pain, the presence of mucus and pus-corpuscles in the urine, of oxalate of lime or uric acid, with the full proportion of urea, and the absence of tube-casts, indicate the nature of the case.

(β) Of the different forms of Bright's disease from each other. The discrimination presents in simple cases little or no difficulty. The points to be attended to are the history of the patient; the amount and characters of the urine; the presence or absence of dropsy; and the nature of the complications. The previous occurrence of exanthematic affections, of chronic wasting disease, or of interperance, gout, or plumbism, would afford some obvious indications. The mode of origin and progress of the malady is very important. Thus a case commencing actually with dropsy and diminution of urine is inflammatory; one of less acute character with polyuria is waxy; and one commencing insidiously, with no marked symptom until perhaps convulsions or dimness of vision appeared, would be an example of cirrhosis. The leading symptoms of the *inflammatory* variety are diminution of urine; an abundance of albumen and of epithelial tube-casts, with diminution of urea; and marked dropsy. Of the *waxy* kidney, the prominent features are early and persistent polyuria; waxy degeneration of other organs; and absence of dropsy. In the *cirrhotic* form the insidious commencement; the gradual development of vascular and cardiac changes; with in the later stages, in many cases, polyuria, are the most important phenomena. Other indications may be gathered from the complications of each form of Bright's disease. It must be remembered that mixed forms frequently occur, and that in these careful inquiry and patient investigation are essential to the establishing of a correct diagnosis.

PROGNOSIS.—The prognosis, though always grave, varies in the different forms of Bright's disease. In the *inflammatory* affection it is least unfavourable, although this affection in the most

immediately dangerous. During its first stage we may always hope for complete recovery, especially in cases of post-scarlatinal origin. Of forty-one successive cases treated by the writer in the Royal Infirmary, Edinburgh, twenty-two recovered entirely, while twelve died, and seven passed into the second stage. If this be the proportion in hospital cases, which are generally sent there on account of their severity, and are rarely sent in the earliest stages of the disease, it is obvious that the proportion of recoveries must be much larger in private practice. When the disease reaches the second stage, the prognosis is more grave, complete recovery being rare, and death sometimes taking place from sudden or gradual increase of the symptoms, or from intercurrent affections. But even in this condition complete recovery may be brought about, and in many cases the patient goes on for long periods, presenting few symptoms to attract attention. In the third stage the prognosis is entirely unfavourable, the system becoming steadily more deteriorated and death occurring, either from the direct effects of the disease, or from complications. Still, even such cases often go on for long periods, if placed under favourable hygienic and therapeutic conditions.

In the *waxy* form the prognosis must almost always be unfavourable, although the malady is never rapidly fatal. On the contrary, its course is always chronic, in some cases extending over five or even ten years. The fatal result is due to complications more frequently than to the disease itself. Recovery probably sometimes takes place, but only when the cause of the degeneration is removed, and the general surroundings of the patient are favourable. It is certain that the liver and spleen may to a large extent recover from waxy disease, and recovery has been witnessed in cases which presented all the symptoms pointing to implication of the kidneys.

In the *cirrhotic* form the prognosis is very unfavourable, but the progress of the disease is so slow that it is often inadvisable to say anything about it to the patient, as the fatal result may be long deferred. It must, however, be kept in view that the disease may be far advanced before its existence is made out.

Among the symptoms and complications which are fitted to cause special alarm when they occur in connection with any of the forms of Bright's disease, we must recognise suppression or great diminution of urine, especially if accompanied by nervous phenomena or general dropsy; uræmia, more particularly its chronic form, and acute inflammations and hemorrhages. Retinitis albuminurica is always a very serious symptom, except when it occurs in pregnant women.

TREATMENT (1) Of the *inflammatory* form. The objects to be kept in view are to arrest the inflammatory action, to remove the inflammatory products from the kidneys; and to obviate the deleterious effects upon the system generally of the accumulation of effete materials. One remedy or plan of treatment may meet more than one of these indications. The most useful means of subduing the inflammatory action, or at least the congestion which attends it, are local blood letting by means of leeches or wet cups, dry

cupping; and the application of hot fomentations, poultices, and counter-irritants. Blood-letting is only serviceable in the early stage of the disease, or when severe exacerbations with suppression of urine occur. Poultices or hot fomentations are of use in the same circumstances. Counter-irritation is helpful in the more chronic conditions. Iodine and croton oil injection are the best fitted for its induction, whilst cantharides must be avoided on account of its tendency to irritate the kidneys.

The removal of the inflammatory products which block up the uriniferous tubules is of the utmost importance, and is in the great majority of cases best effected by means of diuretics. Water and diluent drinks are the safest, and are sometimes found sufficient. The medicinal diuretics must be non-irritating, and the best of all is digitalis, which may be given safely even when the urine is bloody. It may be administered in the form of infusion, tincture, or made up into a pill. Of the infusion from a drachm to an ounce, of the tincture from five to thirty minims, of the powder from half-a-grain to two grains, should be given three times a day. The infusion or the tincture may be combined with spirit of nitrous ether, with acetate of potash, or with tincture of perchloride of iron. Its action is often favoured by the addition of squill and carbonate of ammonia. Sometimes it happens that diuretics do not suit the case, the urine becoming diminished and more bloody under their use, and in other cases the symptoms become so urgent that death might take place before there would be time for diuretics to act. In either of these conditions relief must be obtained by the bowels or skin. The bowels are best acted upon by means of from twenty grains to a drachm of the compound jalap powder, or one-twentieth to half-a-grain of elaterium. The action of the skin may be excited by the use of acetate of ammonia or antimony; but phlebotomy, hot air, vapour-baths, and the wet pack are the most efficient agents. Throughout the whole course of the disease constipation should be avoided, and the action of the skin encouraged. When the disease has become less acute, and certainly when dropsy persists during the second stage, other diuretics are of the utmost value, particularly the acid tartrate of potash, the oil of juniper, and the decoction of broom. Iron must be assiduously administered, to make up for the waste of the materials of the blood. Gallic acid, ergot, and belladonna have all been praised as tending to diminish the discharge of albumin resulting from a persistent chronic inflammation of the tubules. The treatment of special symptoms and complications will be considered after indicating the general management of the other varieties of Bright's disease.

The diet during the earliest stages should be easily assimilable, and not too rich in nitrogenous elements. Milk is, as a rule, well borne. Some practitioners laud skimmed milk as an unfailing remedy in the disease. It is a good diuretic, and, when it suits the stomach, a good article of diet, but possesses no other therapeutic virtue. In the more chronic stages the food should be of the most nourishing kind, and a moderate allowance of stimulants may be needed.

(2) In the treatment of the *waxy form*, the most important indication is to seek to remove the cause of the degeneration, if still existing. If there be disease of bone or chronic abscess it must, if possible, be cured; constitutional syphilis must be combated by appropriate remedies. The tincture of perchloride of iron, quinine, *ana vomica*, and such combinations as Easton's syrup of the phosphates, are useful. The patient must also have good food, and should lead an easy life.

(3) In the *cirrhotic form* it is probable that no remedy we at present possess can influence the pathological process, although arsenic and alkaline remedies, and particularly iodide of potassium, enjoy a certain reputation. It is of course the duty of the skilful physician to obviate the results of the morbid process. It is obviously of great importance to avoid the causes of the disease. Lead-poisoning should be avoided; the gouty tendency kept in check; and the abuse of alcohol forbidden.

(4) In the management of the *combined forms* of Bright's disease these plans of treatment must be conjoined according to circumstances, but, on the whole, treatment is much less successful than in the simple cases. In the combined waxy and inflammatory affection, for instance, it is not uncommon for dropsy to persist, although the diuretics bring the urine up to or above the natural standard.

(5) With regard to the special symptoms and complications of Bright's disease, the sickness and vomiting are best relieved by counter-irritation over the stomach; and by giving ice, milk, and hydrocyanic acid internally. These symptoms are, however, often very intractable. Diarrhoea must sometimes be let alone; at other times it must be treated by means of astringents or sedatives, either administered by the mouth or as enema or suppository. Ascites must be treated as a manifestation of dropsy, and occasionally the abdomen requires tapping. Peritonitis must be combated by hot fomentations and opium, but the latter requires great care in its administration. All through the disease in all its forms hæmætic tonics are demanded; iron in some form should be constantly administered. For hæmorrhages the pernitrate of iron, local astringents, ergot and ergotine, gallic acid, or acetate of lead must be tried in various combinations. The best results have followed the use of ergotine in 3- to 5-grain doses injected subcutaneously. The irritating effects sometimes observed after the subcutaneous injection of ergotine may often be obviated by boiling the solution, or by the addition of a minute quantity of salicylic acid. Hydropericardium and pericarditis must be treated in the usual way. The vessels and the heart are not amenable to treatment. Bronchial catarrh must be carefully attended to, by the avoidance of exposure to cold; by the application of counter-irritation externally; and by the internal administration of expectorants. Œdema of the lungs must be treated by counter-irritants, and by remedies fitted to reduce the general dropsy. Pneumonia, phthisis, and pleurisy must be treated on ordinary principles. Hydrothorax may demand paracentesis. General dropsy is one of the most important complications, and should be combated by means of

diuretics, purgatives, and diaphoretics; in many cases puncture of the oedematous parts is demanded. When puncture has been determined upon, precautions must be taken to avoid inflammation. Eczema and erysipelas, when they occur, should be dealt with according to the principles of the art. Headache is relieved in different cases by iron, by hot or cold applications to the head, by quinine, or by inhalation of a few drops of nitrite of amyl. When uræmia occurs in acute inflammatory conditions, or with suppression of urine, dry-cupping or wet-cupping over the renal regions should be tried, along with free purgation and hot-air baths and, especially in puerperal cases, general blood-letting. Bromide of potassium should be given in drachm doses, and if convulsions be severe, the patient must be kept under the influence of chloroform. In the more chronic and gradually advancing form of uræmia, counter-irritation at the back of the neck and over the scalp sometimes appears to be useful. But treatment is not so often of advantage in this as in the other form. In the eye-affections, iodide of potassium enjoys some reputation. Hemorrhagic apoplexy demands no special measures for its treatment.

T. GRAINGER STEWART.

BROMISM.—**DEFINITION.**—Bromism is the term applied to the morbid effects produced by the administration of the salts of bromine under certain circumstances.

DESCRIPTION.—The effect of the salts of bromine, when administered in medicinal doses, is to reduce nervous activity; and thus, with a certain amount of anæsthetic influence, to promote rest and sleep. When such doses have been long continued, or in certain idiosyncrasies, or when excessive doses are administered, results are produced which constitute a state of disease, and to this condition the term 'bromism' is applied. These results are manifested on the brain and spinal cord; on the skin, on the mucous membranes and glandular structures; and on the organs of circulation and respiration.

1. *On the Brain and Spinal Cord.*—When the therapeutic action intended to be obtained from the use of a salt of bromine is exceeded, the quiet or sleep becomes more pronounced, and there is more or less constant somnolence; the memory becomes impaired, words being forgotten or misplaced, whilst written and spoken language is confused, the tongue is tremulous, and speech is difficult. The gait becomes feeble and staggering, with inability to control movement, and somewhat resembles the condition observed in locomotive ataxy. The special senses—sight, hearing, taste, and touch—are impaired; reflex excitability is diminished, and this is especially observed in the fauces, occasionally to such an extent as to cause difficulty in swallowing. Sexual feelings are diminished or altogether suppressed. The general aspect of a case of well-marked bromism much resembles one of senile imbecility.

2. *On the Skin.*—A very frequent result of the internal use of the bromides is a follicular eruption of the skin, closely resembling acne, which is generally situated on the face, chest,

and shoulders. When the use of the drug is continued, the acne becomes aggravated, and boils appear. A more rare form of skin-disease similarly caused has been described by Dr. Cholmeley, Mr. Hutchinson, and M. Voisin. This disease appears as vesicles, which become aggregated into clusters or patches. These proceed to suppuration, and are soon followed by scabbing their base being slightly raised, hard, sometimes ulcerated, and surrounded by a red areola. In a later stage the eruption presents the appearance of dusky red stims. It has been observed more especially on the limbs and head. Eruptions having more or less the characters of erythema and of eczema have also been described as following the use of these agents.

3. *On the Mucous Membranes and Glandular Structures.*—Dryness of the mouth and tongue is often experienced in bromism; but in some cases there is said to be an increased flow of saliva. Nausea, flatulence, eructations having a saline taste, heat and fullness at the epigastrium, and occasionally gastric catarrh and diarrhoea, have been observed; it is said that acute enteritis and even a typhoid condition have occurred.

4. *On the Organs of Circulation and Respiration.*—The salts of bromine are said to produce contraction of the capillaries. The skin may present a peculiar pallor, and the extremities feel cold. The action of the heart is rendered slower and weaker; and may even cease altogether, under the continued operation of these drugs. The action on the respiratory organs is similar to that upon the heart. It has been observed that bromine—recognised by its peculiar odour in the expired air—is eliminated from the respiratory mucous membrane. Bronchial catarrh occurs, and instances are recorded in which pneumonia is said to have followed and proved fatal.

It must be remembered that, although it has been thought desirable to discuss separately here the effect of these drugs on the several systems, these effects are combined in various degrees. In some cases the affection of the skin is alone noticeable; in others, that of the nervous system; while in a third class there is produced a combination more or less of all the phenomena, constituting what may be called a *cachexia*. In such cases we find loss of flesh, strength, colour, and mental power; paralysis of the muscles; loss of reflex and general sensibility and of the functions of the special senses; complete apathy and general prostration, the countenance having a semi-idiotic expression; coldness of the extremities; and gradual failure of the heart's action.

PATHOLOGY.—The condition just described is but the extreme effect of the ordinary physiological action of the salts of bromine. This condition may be due either to idiosyncrasy—that is, to undue susceptibility on the part of the individual—or to the administration of large quantities of the drug, either in medicinal doses for a long period, or in excessive doses administered within a short time. The individual susceptibility may depend upon the want of capability to eliminate the drug; on the general state of health; or on the presence of a disease

which resists its action. Under these circumstances, as well as in the presence of certain modifying influences, such as the action of other remedial agents simultaneously administered, it is difficult to fix upon the amount of a bromine salt capable of producing morbid symptoms in any given individual. The writer has seen a nightly dose of ten grains of bromide of potassium, continued for some weeks, produce marked somnolence during the day, and impairment of memory; whilst it has required the enormous doses of 200 or 300 grains a day, which seem to be administered on the Continent, to produce the extreme effects above described. The rapidity with which these effects are produced, constituting the *acute* and *chronic* forms of bromism, will depend on the amount and frequency of the dose, and on the susceptibility of the individual. The effect of a sudden considerable increase in the dose has been observed by the writer in a case which first directed his attention to the subject of bromism in 1872. This case he saw in consultation with Mr. Alfred Burton. Half-drachm doses of bromide of potassium had been taken twice a day for several weeks, when by mistake the quantity of the drug was doubled; then, after three days, symptoms closely resembling senile imbecility were rapidly developed.

DIAGNOSIS.—Recognising the value of the bromides, and the frequency with which they are used, it is extremely important that the peculiar results which they are capable of producing should be borne in mind; for if they are not recognised in time, and if the use of the drugs be persisted in, disastrous effects which might otherwise be avoided will follow. Without going into details of diagnosis, it will probably be sufficient to point out the necessity for remembering that the symptoms which have been described above can be produced by the use of bromides; and that when such a combination of symptoms does occur during their use, it is highly probable, in the absence of disease capable of accounting for them, that the symptoms have originated from the operation of those agents.

TREATMENT.—This consists in stopping the use of the drug, and hastening its elimination by promoting the action of the kidneys and other excreting organs. It is said that arsenic in combination acts as a preventive of the eruptions.

The above description refers to the effects of bromide of potassium, but like effects are produced by other salts of bromine, though to what extent by each has not yet been ascertained.

R. QUAIN, M.D.

BROMIDROSIS (*βρῦμος*, a stench; and *ἰσπῆς*, sweat). A term for fetid perspiration. See PERSPIRATION, Disorders of.

BRONCHI, Diseases of.—The diseases of the bronchi may be discussed in the following order.—1. Acute inflammation; 2. Chronic inflammation; 3. Plastic inflammation; 4. Dilatation; 5. Narrowing or obstruction; 6. Cancer.

1. **Acute Inflammation—Acute Bronchitis—Acute Bronchial Catarrh.**

DEFINITION.—An acute inflammation or congestion, general or partial of the bronchial tubes

ÆTIOL.—The causes of acute bronchitis may be classed as (a) *predisposing* and (b) *exciting*.

(a) Of the *predisposing* causes age is one of the most important. The disease is indeed confined to no period of life, but it is most frequently met with in the young and the old, and in these subjects it assumes its most serious characters. The imperfect development of the infant, and the diminished vitality of the aged, seem to render them especially liable to attacks of bronchitis, and to make the disease exceptionally fatal in them. Sex appears to have no influence as a predisposing cause. The habits of life have an important influence in the causation of bronchitis. The practice of living in heated rooms, especially where gas is largely consumed, and of breathing the vitiated atmosphere produced by the assemblage of large numbers of persons in apartments, is undoubtedly a fertile predisposing, as well as exciting, cause of the complaint; so also is the practice of keeping children too much within doors on the one hand, or, on the other, of exposing them to inclement weather when insufficiently clad. Temperament can scarcely be considered a predisposing cause, but the state of the general health exercises a powerful influence. A weakly constitution, or one weakened by overwork, improper food, &c., predisposes to bronchitis, whilst such affections as Bright's disease, gout, and diseases of the heart, alike favour its occurrence. Again, certain occupations are favourable to the development of bronchitis. Independently of the fact that living or working in heated and confined rooms predisposes to the disease, such occupations as lead to the inhalation of irritating particles, as those of steel, cotton, &c., give rise to it. The climate most favourable to the production of bronchitis is probably that which is at the same time both cold and damp, and where sudden variations of temperature occur. The seasons of the year in which it prevails most are the late autumn, the winter, and the early spring.

(b) **Exciting causes.**—Although undoubtedly cold directly applied to the surface of the body is in a large number of cases the exciting cause of bronchial inflammation, still the transition from cold to heat—passing from a cold atmosphere to a heated one—is a large factor of the disease. There can be little doubt that bronchitis is often produced directly by the effects of heated and vitiated air on the bronchial membrane, and on the system at large; and that in the latter instance, the affection is merely a local manifestation of a general influence. Bronchitis may also be caused by the direct action of irritants contained in the air—as irritant vapours, minute particles of steel, cotton, or ipocuanha, and the emanations (pollen) from flowering plants. Again, morbid conditions of the blood, the result of specific febrile affections, act as exciting causes of the disease; as do also the poison of syphilis, and the altered condition of the blood produced by gout. Bronchitis is, moreover, a constant accompaniment of influenza.

ANATOMICAL CHARACTERS.—The mucous membrane is mainly affected in acute bronchitis, but morbid changes may be produced in the deeper structures. The mucous membrane is red—the

redness being arborescent, streaked, or mottled, but not usually spread uniformly over a large surface. The injected condition of the membrane does not, as a rule, extend into the finer bronchial tubes, but in some cases where there have been frequent attacks of inflammation, the smallest bronchi have a red appearance. The membrane is sometimes thickened and soft, but ulceration is very rare. The tubes are generally found more or less filled with secretion, either frothy mucus, muco-pus, or even actual pus. Sometimes the secretion is very abundant, filling all the tubes. Fibrinous masses are occasionally met with, which may form casts of the tubes. Collapse of portions of lung-substance—lobules or whole lobules of the lungs—is not unfrequently found, as are also patches of lobular pneumonia. The venous system and the right side of the heart are overloaded, and the blood is dark. In many cases fibrinous deposits are found in the cavities and great vessels of the heart.

In speaking of the pathology of bronchitis, it is necessary to refer to the distribution of the bronchial blood-vessels. The bronchial arteries when they have fairly entered the lungs have no accompanying veins. The so-called bronchial veins are some small vessels which return the blood supplied to the structures about the roots of the lungs. The blood which is supplied to the bronchial tubes, when they have commenced their divisions, passes into radicles of pulmonary veins, and is returned directly to the left side of the heart. The question whether there is a communication between the bronchial arteries and the pulmonary artery, is still *sub judice*. If such communication exist, it is only slight. The blood of the bronchial arteries, after supplying the mucous membrane and other structures of the tubes, passes, either wholly or in very large part, to the left side of the heart, not having circulated through the aerating portion of the lungs. The circumstances of this anatomical arrangement are most important in a practical point of view. Anything which embarrasses the circulation on the left side of the heart—such as mitral regurgitation—must necessarily cause a very loaded condition of the bronchial vessels, and all physicians are familiar with the form of bronchitis which is so common in these cardiac affections. The congested mucous membrane, and the profuse bronchial secretion, are the result of the direct impediment to its circulation which the blood meets with, from passing at once into vessels which go straight to the left side of the heart. The relief often afforded in this form of bronchitis by the exhibition of digitalis, is explained by the circumstance above referred to.

SYMPTOMS.—The symptoms of acute bronchitis vary according as the larger or smaller tubes are affected. The disease attacks, first, the larger and medium-sized tubes; and, secondly, the smaller ones. To this latter form of the affection the name of *capillary bronchitis* has been given.

1. *Acute bronchitis of the larger tubes.* The attack is usually ushered in by symptoms of catarrh,—sneezing, lachrymation, a sense of fulness about the nose and eyes, with frontal headache; the throat becomes dry and sore, and then increased secretion sets in; the follicles at the

back of the pharynx become enlarged, the upper part of the larynx is often involved, there being slight hoarseness; and the affection gradually creeps down into the bronchial tubes. The disease is not ushered in by decided rigors, but chills and sometimes shiverings are experienced; the pulse is not much affected, but its frequency is increased in some cases; there is a general sense of malaise, as well as a want of energy. When the disease has set in fully certain local symptoms are found. More or less pain is felt behind and above the sternum; the sensation is increased by a deep inspiration; the pain shoots at times over the chest in the direction of the larger bronchial tubes; and there is a tickling or unpleasant irritation felt behind the sternum, which gives rise to cough. Dyspnoea is not a marked feature of this form of bronchitis, it exists, however, sometimes, and in the most severe cases a sense of oppression, weight, and tightness about the chest is experienced. Cough is one of the earliest and most prominent symptoms; it is at first dry, and there is usually at this period some hoarseness. The cough is paroxysmal, and often very violent; it becomes attended with expectoration as the disease progresses. This varies at different stages of the affection; at first watery and frothy, and almost transparent, it becomes as the disease progresses more consistent, viscid, and opaque, passing through the stages of mucus to muco-pus and pus; it is sometimes distinctly unmineralized. Small streaks of blood are occasionally seen mixed with the sputa. Examined under the microscope the sputa are found in the early stages of the disease to contain epithelial cells from the mucous membrane; and, later, many of the so-called exudation-corpuscles, molecular and granular matter, pus-cells, and occasionally blood-discs.

In the milder cases of this form of bronchitis there is but little general disturbance; and even in the more severe cases the febrile reaction is not usually very great. The pulse rises a little, but does not become very frequent; the temperature rarely becomes high; there is in many cases but little interference with the appetite. A general feeling of depression, which in some cases is very marked, is usually experienced.

2. *Acute bronchitis of the smaller tubes—Capillary bronchitis.* This is a very formidable disease. It attacks the finer bronchial tubes, and probably extends to their smallest ramifications. Its symptoms are very grave. Some of the worst cases of capillary bronchitis are met with in connexion with emphysema of the lungs. It may be an extension of inflammation from the larger tubes; or the capillary tubes may be attacked simultaneously with the larger ones, or alone. The early symptoms are more severe than those of ordinary bronchitis, and rigors are more common. Dyspnoea is marked; it may vary from mere rapid respiration to constant or paroxysmal orthopnoea. The respirations may rise to fifty in a minute. Cough is almost continuous, at times becoming very violent and most distressing. Expectoration is attended with difficulty. The sputa soon become very abundant, and rapidly assume a purulent character; or they are very viscid and ropy.

The general symptoms are very severe. The

ever is high—the temperature reaching to 103° Fahr. and upwards; and the pulse is frequent, rising to 120 or 140. The temperature rarely attains the height which characterises acute tuberculosis or pneumonia. There are often profuse perspirations, and in some cases excessive debility is felt. If the disease progresses unfavourably, symptoms of very imperfect aëration of the blood come on. The face becomes turgid and bloated, the lips and ears get livid, the veins are distended, the temperature falls, cold clammy perspirations break out, the pulse becomes very small and rapid, delirium supervenes, the respiration is shallow and catching, and the patient dies of asphyxia, and from the presence of fibrinous clots in the heart and great blood-vessels.

PHYSICAL SIGNS.—The physical signs of both forms of acute bronchitis may be referred to together. Inspection reveals little of practical value in simple bronchitis. The chest-form is not altered. In severe cases the abdominal movements are in excess. The costal movements are frequently those of elevation rather than expansion. In extreme cases the lower end of the sternum and the connected cartilages sink with inspiration, while the expiration-movements are slow, laboured, and inefficient. If the hand is applied to the chest, rhonchal frémittus may be often felt, sometimes over a large area. The percussion-sound may be somewhat exaggerated from over-distension of the lungs, especially in children, not appreciably altered, or deficient in resonance, owing to the accumulation of secretion at the bases of the lungs, to œdema or congestion (as in typhoid fever), or to pulmonary collapse. In young children a sound resembling the cracked-pot sound may be occasionally produced, variable in site. The sounds heard in auscultation vary according to the stage of the disease. The breath-sounds are loud when the tubes are free; when the latter are plugged by secretion, they often become feeble or even totally suppressed, from closure of a tube leading to a portion of the lung. The adventitious sounds of bronchitis include the various rhonchi, dry or moist: the dry rhonchi are heard in the early stages of the disease for the most part, but when once secretion has set in, the moist rhonchi or râles are more or less extensively heard, depending for their character on the size of the tubes which are the seat of inflammation. Thus they are called *mucoous* when produced in the large tubes, *sub-mucoous* and *sub-crepitant* when produced in the finer ones; the latter term being used to characterise the râles of capillary bronchitis. When the large bronchial tubes are filled with a secretion which is not viscid, the sounds may have a rattling character. The various rhonchi may be heard over different parts of the lungs at the same time, according to the seat and stage of the bronchitis. In capillary bronchitis sub-crepitant râles, accompanying inspiration and expiration, are abundantly heard towards the bases of both lungs especially. As a rule there is no displacement of organs in bronchitis, but the diaphragm is sometimes depressed from great distension of the lungs, and the heart is occasionally displaced towards the right.

DIAGNOSIS.—The diagnosis of acute bronchitis,

except in a few instances, presents no great difficulty. In the early stages of whooping-cough it is impossible to decide whether the case is one of simple bronchitis or not, but subsequently the paroxysmal character of the cough settles the point. In some cases of bronchitis occurring in children the breathing may resemble that of croup, but here the presence of catarrh; the wheezing nature of the respiration; the absence of much fever; the characters of the sputa obtained by wiping the back of the tongue, and its freedom from membranous shreds; and the physical examination of the chest indicating the presence of rhonchi, will be sufficient to establish a diagnosis. From laryngitis the discrimination is not difficult.

Pneumonia may generally be easily diagnosed from capillary bronchitis, with which form it can perhaps be alone confounded. Capillary bronchitis is not ushered in, as pneumonia usually is, by a well-marked and prolonged rigor; the general febrile disturbance is less, and the temperature not so high, moreover the absence of dulness on percussion, and of increased vocal resonance and frémittus will aid in the differentiation. From lobular pneumonia in children the diagnosis is not always easy. In this disease there is often no dulness to be perceived on percussion; whilst, on the other hand, in bronchitis dulness may exist from pulmonary collapse.

The diagnosis of capillary bronchitis from acute phthisis often presents difficulties. The main points to be relied on, independently of the family history, which may aid, are that in capillary bronchitis the fever is less and the temperature lower; signs of apnoea soon come on; and there is free expectoration of muco-purulent matter. In one form of acute phthisis there is evidence of pneumonic consolidation, followed by signs of the formation of cavities. In the milky tubercular form there are in many cases scarcely any physical signs except râles, most marked at the apices of the lungs.

PROGNOSIS, DURATION, TERMINATION, AND MORTALITY.—The prognosis in an ordinary case of bronchitis is favourable, but when the disease occurs in the very young or the aged the prognosis should always be guarded. In the milder forms the affection may last only a few days, or two or three weeks. Severe cases are more protracted. The disease may terminate in perfect recovery, in death, or by passing into the chronic form. It may be the starting point of emphysema of the lungs, or of certain forms of phthisis. The mortality is much influenced (1), by age, being greatest in the very young and the very old; (2), by the previous state of health, which, if lowered by any circumstances, will render recovery more doubtful; (3), by the extent of the inflammation, especially when the disease is of the capillary form; (4), by the existence or non-existence of any organic disease of the heart, lungs, or kidneys; (5), by the disease being epidemic or otherwise; and, lastly, by the time the case has come under treatment, whether early or late.

TREATMENT.—In the treatment of bronchitis regard must be had to the constitutional condition of the patient. Care must be taken to ascertain whether the disease is secondary to

some organic affection; or the result of mechanical irritation, of the presence of gout or rheumatism in the system, or of influenza; or whether it arises idiopathically. The treatment of the disease as a primary affection will be considered first.

In an ordinary case of acute bronchitis it is very desirable to keep the patient confined to his room and, if the case is at all severe, to his bed. The temperature of the apartment should be maintained at from 60° to 65° Fahr. A higher temperature than this is generally not favourable to the progress of the case. In the early stages of the attack it is well to allow the air of the room to be more or less saturated with steam. A free action of the skin should be promoted; and for this purpose warm drinks, with or without some form of alcohol or some diaphoretic medicine, may be given; or a hot-air bath may be used in bed. Great relief is often experienced from the application of a large mustard or mustard and linseed-meal poultice to the chest; and it is well, if mustard is applied first, to apply immediately afterwards a large hot linseed-meal poultice, to be renewed every few hours. This constant application of warmth and moisture to the chest is often productive of very great relief to the symptoms.

Cases of acute bronchitis do not require venesection, nor is the application of leeches often, even if ever, called for. Severe counter-irritation is moreover to be prohibited. It is generally desirable to act on the bowels, and a mercurial, followed by a saline purgative, will often be of great service. In the old and debilitated, as also in the young, all lowering treatment must, however, be avoided. In the early stages of the affection, before secretion has commenced, and when the mucous membrane is dry and the cough hard, diaphoretics with ipocacanha may often be given with advantage; but as soon as secretion is fairly established, carbonate of ammonia, spirits of chloroform, ether, cascarrilla, senega, or such-like drugs should be administered. Indeed in almost every stage of bronchitis carbonate of ammonia is one of the most valuable remedies we possess. Care should be exercised, especially with the aged, that nothing should be given which will so nauseate as to prevent food being taken. In the exhibition of medicines to alleviate the cough, regard must be had to the condition of the patient and the stage of the disease. Opium in all its forms should be given with caution, especially in the young and old. It no doubt often succeeds in checking cough, but in doing so it also checks expectoration, and causes an accumulation in the bronchial tubes, which sometimes becomes very dangerous to life. Chloral in small doses is often of great use for relieving cough, and it may be combined with oxymel of squills. It has also a good effect in allaying spasm of the tubes, if this exist. In some cases of bronchitis the question of procuring sleep becomes an important one. Opium in its various forms is generally inadmissible, in consequence of its tendency to increase the condition of apnoea, but chloral may be given with safety, and the recovery of a patient may sometimes be dated from the sleep which this agent procures.

In reference to the exhibition of alcoholic stimulants, except in the early stages, and in certain cases dependent on a gouty or rheumatic condition, they should usually be given in smaller or larger quantities. They increase expectorating power, and ward off the tendency to apnoea. In the old they are especially called for, and, together with carbonate of ammonia, should form the main therapeutic agents to be relied on. In the treatment of capillary bronchitis, ammonia and alcoholic stimulants should be exhibited from the commencement, and the quantity must depend on the symptoms of each case. There is one source of danger in capillary bronchitis which should always be borne in mind, viz., the formation of fibrinous clots in the heart and great blood-vessels. These deposits become the proximate cause of death in many cases, and they are especially liable to form when there is emphysema of the lungs. Their presence may often be diagnosed during life from the respiration becoming very rapid, shallow, and laboured: the pulse being quick, weak, and small, although the heart may at the same time be felt beating vigorously; the voice becoming feeble; and the mental faculties seriously impaired. After death a large portion of the cavities of the heart may be found occupied by these deposits, the calibre of the pulmonary artery and aorta being also materially diminished by them.

In many cases of bronchitis, when the acute symptoms have passed off but the secretion continues profuse, as well as in those cases called bronchorrhoea, the exhibition of iron is often of great service. It seems to give tone to the relaxed capillaries of the mucous membrane, and to diminish the secretion. It may be given in combination with carbonate of ammonia, in the form of the ammonio-citrate; or the tincture of the perchloride with ether or spirits of chloroform may be employed, or the ethereal tincture of the acetate (Ph. Ger.), which is a very valuable preparation in some cases.

Inhalations are useful for allaying cough in the earlier stages of the affection, or for the relief of spasm. In some cases of severe bronchitis where apnoea has been threatened, recovery has followed the exhibition of large doses—half an ounce—of turpentine. In this dose, however, it sometimes produces alarming symptoms, and it is perhaps better to exhibit it in smaller quantities tentatively. An emetic may be serviceable, especially in children, if the tubes are much loaded. Children suffering from severe attacks of bronchitis should not be allowed to sleep long, for fear of dangerous accumulation in the tubes, and care should be taken that the secretions do not collect about the larynx of the mouth.

Patients should not be kept on a low diet even at the beginning of an attack, and as the disease progresses the quantity of food allowed may be increased according to the appetite. In the treatment of gouty bronchitis, or bronchitis associated with a tendency to the formation of uric acid in the system, colchicum and the alkalis must be given, and the general measures used which are applicable to the constitutional condition. If bronchitis depend on a gouty state,

it will not yield to the ordinary treatment, but when its cause is recognised and the appropriate remedies are administered, the symptoms usually soon begin to improve.

In the cases of bronchitis which are connected with heart-disease, and especially with mitral regurgitation, digitalis is often of great value. By stealing the action of the heart it relieves the overloaded pulmonary veins, and thus directly diminishes the congestion of the mucous membrane, as mentioned in the paragraph relating to the pathology of the disease.

It is impossible in the scope of this article to refer especially to the treatment of bronchitic attacks arising from the various kinds of mechanical irritation. There is, however, one form of bronchitis which may be mentioned, viz., that connected with hay-fever, arising either from the inhalation of pollen, or caused by some peculiar atmospheric influence acting on a peculiar nervous system. It is very difficult of cure. In the writer's experience no remedies seem to have any particular influence over it, and it is usually only to be relieved by removing the patient from the exciting cause of the affection. In the treatment of bronchitis depending on constitutional syphilis, the appropriate measures for that affection must be resorted to.

2. Chronic Inflammation—Chronic Bronchitis—Chronic Bronchial Catarrh.

DEFINITION.—A chronic inflammation or congestion, more or less extensive, of the bronchial tubes.

ÆTIOLOGY.—Chronic bronchitis very frequently results from repeated attacks of the acute disease, but it may be chronic from the beginning. Emphysema of the lungs, dilated bronchi, and phthisis are causes of the complaint, as are also various forms of heart-disease, and some blood-affections, such as gout. The inhalation of irritating particles gives rise to chronic bronchitis; and it is also met with in connexion with chronic alcoholism. It is most common amongst the old.

ANATOMICAL CHARACTERIS.—The bronchial mucous membrane is discoloured, being of a dull red tint, greyish, or brownish. The discoloration is for the most part partial, but sometimes evenly, diffused. There is swelling and increased firmness of the mucous membrane, and the sub-mucous tissue in old-standing cases becomes infiltrated and indurated. The fibrous and muscular tissues are hypertrophied; the cartilages in the larger tubes are sometimes calcareous; and there is generally more or less emphysema of the lungs.

SYMPTOMS.—The symptoms of chronic bronchitis vary greatly in different cases. They resemble in kind those of the acute affection. There is cough, expectoration, pain, soreness or uneasiness behind the sternum, with more or less dyspnoea. The constitutional symptoms may be very slight, scarcely any effect on the general health being apparent; or they may be very severe. Three forms of chronic bronchitis are recognised clinically:—1. That which includes the ordinary cases of the disease, varying much in severity; 2. that characterised by excessive secretion—*bronchorrhœa*; 3. that form which is called *dry catarrh*.

1. In the first form of chronic bronchitis the

cough is at first slight, perhaps only occurring during the winter, being altogether absent in the summer. After a time the attacks become more frequent, and at last the patient is never free from the affection, which is aggravated at times. The cough in such cases is more or less severe, but usually most so in the morning. It is often paroxysmal, and sometimes very violent. The expectoration, in some cases being scanty, viscid, and difficult to discharge, is in others, especially old-standing cases, copious and easy. The sputa vary much both in appearance and quantity. They may be yellowish-white mucopurulent matter, or more decidedly purulent, of a greenish-yellow or bright or dark green colour; they are but little aerated, sometimes not at all, so that they sink in water; at times they are nummulated and quite opaque. In some cases the expectoration is fetid, constituting the form of the disease denominated 'fetid bronchitis,' the odour resulting either from sloughs of minute portions of the mucous membrane, or from chemical changes taking place in the sputa. Occasionally streaks of blood are met with. Microscopically the sputa are found to consist of epithelium, pus-cells, and granular matter, with at times blood-corpuscles.

The constitution does not suffer much in mild attacks, but when chronic bronchitis is permanent and general, the system at large sympathises more or less severely: the appetite fails, sleep is disturbed by the cough, emaciation sets in and sometimes becomes marked, but it does not proceed beyond a certain point, unlike that of phthisis, which is usually progressive. In all cases of chronic bronchitis there is great risk of an acute attack coming on, especially amongst the aged. These attacks are very dangerous, in consequence of the rapid extension of the disease throughout the lungs, and its asphyxiating character.

2. The second class of cases is characterised by excessive secretion from the bronchial tubes—*Bronchorrhœa*. This form is often met with in the old and feeble, and especially in cases of valvular disease of the heart. The cough is paroxysmal, and attended with the expectoration of a large quantity of thin watery glairy fluid, or of thick ropy gluey matter, like white of egg. The quantity expectorated is sometimes very large. This form of bronchitis may cause death somewhat suddenly by apnoea. During the paroxysms of cough there is dyspnoea, but at other times it is absent, except when heart-disease exists. The constitution suffers little, and the flux seems sometimes to be beneficial in cases of obstructive cardiac disease.

3. The third variety, or *Catarrhæ sec*, is characterised by very troublesome cough, oppression of breathing, tightness of the chest, and sometimes severe dyspnoea. Expectoration is either absent or very scanty, the sputa consisting of small masses of tough viscid semi-transparent mucus. There is usually no febrile disturbance. The disease is met with in gouty people, and is often associated with emphysema of the lungs. Pathologically it seems to consist in a congested condition of the bronchial tubes.

PHYSICAL SIGNS.—Inspection reveals nothing abnormal in the form or size of the chest, unless

emphysema of the lungs is present. The expiration in long-standing cases is usually deficient; the chest being raised more than in health. Expiration is often prolonged. Rhonchal fremitus may be felt more or less, depending on the state of the bronchial tubes. There is often increased resonance, from the presence of emphysema. The breath-sounds are more or less changed; they are harsh and loud, and the expiration is prolonged in cases that have existed for a considerable period. The rhonchi vary; they are dry, coarse, moist, or bubbling according to the condition and contents of the tubes. Vocal resonance varies; it may be bronchophonic, normal, or deficient.

DIAGNOSIS.—There is usually but little difficulty in the diagnosis of chronic bronchitis. The affection is most likely to be confounded with phthisis, but the character and degree of the wasting, and the absence of increased temperature, of hæmoptysis, and of the physical signs of consolidation, will generally enable the practitioner to decide in favour of the less important disease. The main difficulty lies in the diagnosis of cases where the bronchi are dilated; this will be referred to hereafter.

PROGNOSIS.—Although in itself not a dangerous malady, chronic bronchitis becomes so in consequence of the liability which exists to the occurrence of acute symptoms; when once established in middle or advanced age it is almost incurable. The complaint is further serious from its tendency to produce emphysema and dilatation of the bronchi. *Per se* it can scarcely ever be said to kill.

TREATMENT.—No case of chronic bronchitis can be successfully treated without due regard to the constitutional condition of the patient. In some cases it is impossible to cure the disease, and all efforts should be directed towards preventing its extension; alleviating the symptoms to which it gives rise; and warding off acute attacks. Attention must be especially paid to the state of the heart and kidneys; the duration of the affection; the age of the patient; the characters of the expectoration, the state of the lungs, as to the existence of emphysema or other morbid conditions; and the presence of gout or rheumatism. Speaking generally, chronic bronchitis must be treated by the use of a generous diet, with more or less stimulants; by the exhibition of expectorants and tonics; and by the avoidance of all depressing measures. The function of the liver must be looked to, and the administration of a few doses of blue pill with a saline aperient often gives great relief, and alters the character of the bronchial secretion. If gout, or a tendency to the formation of uric acid, is present, colchicum with alkalis and other remedies for gout, such as a course of Friedrichshall or Carlsbad waters, will prove of great service. If cardiac disease exist, whether in the form of valvular incompetence, or of weak, flabby, or dilated heart, digitalis combined with iron frequently produces marked benefit.

In the treatment of ordinary cases of chronic bronchitis, not dependent on any organic disease or constitutional condition, the patient's general health has to be looked to. The affection has a tendency to lower the health and to diminish

strength, and therefore the various tonics may often be given with great benefit. Of these the most useful are quinine, the preparations of iron, and those of *cod-liver oil* is also very valuable in some cases where there is much wasting. The cases of bronchitis marked by excessive secretion are generally best treated by tonics; whilst those where the secretion is slight—cases of 'dry catarrh'—being often associated with a gritty condition of the system, are more amenable to the use of colchicum, the alkalis, iodide of potassium, and mineral waters.

In what may be called the symptomatic treatment of the affection, the various expectorants are useful—carbonate of ammonia, ipecacuanha, squill, cascarella, senega, chloroform, &c., and these may often be beneficially combined with some form of tonic. In many cases of chronic bronchitis the expectorating power is diminished, and stimulating expectorants are of great service. Great caution must be exercised in the administration of opiates and other narcotics or sedatives. When, however, the mucous membrane is very irritable, and when there is but little secretion with a troublesome cough, these remedies are indicated. Opium is of great value, and chloral hydrate is also very useful, as well as, in some cases, henbane and hydrocyanic acid, or, whenever spasm is present, stramonium, lobelia, the ethers, and cannabis indica. Inhalations are sometimes very beneficial, as of the vapour of warm water, iodine, creosote, and other substances. The inhalation of creosote is especially valuable if the expectoration is fetid.

Counter-irritation is one of the most important means we possess of relieving chronic bronchitis. The irritation should not be excessive, but should be long-continued. The application of iodine over a large surface of the chest, so as to keep up a constant slight inflammation of the skin, is perhaps the best that can be used; but other irritants may be tried, such as sinapisms, or the various stimulating liniments.

The general management of the patient is most important. A mild climate should, if possible, be chosen in the winter. The patient should live as far as possible in an atmosphere which is mild and dry. Although some cases are benefited by a moist and warm atmosphere, the majority of cases of chronic bronchitis do better in a drier one. The skin must be carefully looked to, its action should be well maintained, and warm clothing always worn. A moderate amount of some alcoholic stimulant is generally desirable; and the food should be nutritious and of easy digestion. Relief will often be found from wearing a respirator.

3. Plastic Bronchitis.—This is a rare form of disease, and of its particular causes nothing is known. It is perhaps connected with some peculiar diathesis. Sir John Ross Cormack suggests that it may be a variety of diphtheria. It may occur in either sex, and at any period of life, but is most frequent in those who are of a strumous or phthisical constitution. It has been known, however, to attack persons of apparently healthy frame and in the enjoyment of robust health.

ANATOMICAL CHARACTERS.—Plastic bronchitis is anatomically characterised by the formation of concretions in the bronchial tubes. These

concretions consist of fibrinous exudation from the mucous membrane; they form casts of the tubes, and are expectorated. These casts are either solid or hollow, and on examination are always found to consist of concentric laminae. They are, for the most part, poured out into the finer bronchial tubes, sometimes, however, into the larger ones, but never into the trachea. The casts are of a whitish colour, but they are often stained with blood. Microscopically they consist of an amorphous or fibrillar material, with exudation-corpuscles, granular matter, and oil-globules.

Symptoms.—This disease is essentially chronic, but it has been met with as an acute affection in children. At the times when the casts of the tubes are expelled exacerbations occur, the patient being attacked with pain and a sense of constriction across the chest, dyspnoea, and an irritating cough. After a time, varying from some hours to a few days, the dyspnoea becomes very urgent, and the cough very severe, then, after a paroxysm of coughing, it is found that the patient has expectorated some solid material, either with or without blood, usually intermixed with ordinary bronchitic sputa. The dyspnoea and cough now subside, to recur after an interval of a few hours or longer. The disease may last for weeks, months, or even years, marked from time to time by severe accessions, and relieved by the expulsion of further concretions. The matter expelled is often in small masses, but at times casts of bronchial tubes with several ramifications are expectorated. The disease may recur at intervals for many years, the general health in such cases does not seem to suffer, the breathing during the intervals being unaffected. There is, in some instances, an absence of febrile symptoms during the attack, whilst in others the fever is more marked. With the general symptoms are combined the *physical signs*. These are somewhat peculiar. The bronchial tubes being obstructed, portions of lung are deprived of air; the breath-sounds are therefore faint or absent. There may be dullness more or less complete on percussion, from collapse of the lung-substance, or, as occurs in some cases, from localized pneumonia. Apnoea may be threatened if a large tube is blocked up.

Diagnosis.—The diagnosis of this affection turns on the peculiarity of the expectorated matters. Doubtless the disease may be mistaken for ordinary bronchitis or pneumonia, but when once the fibrinous casts of the tubes are observed in the sputa, the nature of the case becomes clear.

Prognosis, Duration, Terminations, and Mortality.—The prognosis, if the disease is uncomplicated, is favourable; but there is great liability to recurrence. The complaint may last for many years, and may terminate in complete recovery. A fatal result generally depends on the presence of some other organic disease, such as phthisis or pneumonia.

Treatment.—But little can be advanced as to the value of any special treatment for this affection. Iodide of potassium is said to have been employed with success. The chief object should be to maintain the general health by hygienic measures, and the exhibition of tonics, such as iron, quinine, and cod-liver oil, especially if there

be any tubercular taint. During the exacerbations the administration of ammonia and the use of inhalants should be resorted to, and the general principles on which ordinary bronchitis is treated should be carried out.

4. **Dilatation.**—**Bronchiectasis.**—This is a rare disease, which arises as a secondary affection. It is often associated with serious pulmonary mischief, and is at times difficult of diagnosis. There are two forms of bronchiectasis, namely *general or uniform dilatation*, and *saccular or ampullary dilatation*.

1. The *general* or uniform bronchiectasis consists in a cylindrical dilatation of one or more of the tubes throughout a considerable portion of their extent. The tubes are evenly widened for the most part, and end abruptly.

2. The *saccular* form of bronchiectasis consists of a globular dilatation of a tube at one point, or at several points. The dilatations vary in size, being from half an inch to an inch or more in diameter. On the tracheal side they usually communicate with a slightly enlarged bronchial tube, whilst on the peripheral side the continuity of the tube is almost or entirely lost from narrowing or actual obliteration. Sometimes the cavities communicate with one another.

The two forms of bronchiectasis often coexist.

The walls of the dilatations undergo changes in the course of the disease. The mucous membrane becomes granular, swollen, and congested; while at a later stage it presents a velvety or villous appearance, and in some cases there is even ulceration with superficial necrosis. The muscular and elastic coats become atrophied, and coincidently with this dilatation increases. At times the wasting of these coats is partial; some portions of the walls retaining their natural volume, and forming bands or ridges elevated above the surrounding membrane. The dilated tubes occasionally present an appearance of hypertrophy; the walls are thickened, but the thickening depends on changes which have taken place in the mucous membrane. The cartilages resist the destructive metamorphoses longer than the other structures, but they sometimes partake of them. The contents of the tubes may be either mucus, pus, or pus, and casts of the minute bronchi are met with. At times the contents are very fetid. Crystals of margaric are occasionally found, and sometimes fragments of pulmonary tissue. It is said that the contents may become calcareous.

Dilatation of the bronchi may be unattended with any change in the surrounding lung-tissue, but, generally speaking, condensation of the latter takes place, either as the result of pressure or of chronic pneumonia. In some instances the tissue forms an abscess, in the centre of which the walls of the bronchus are found, whilst in others the walls of the bronchi and the surrounding tissue are destroyed by gangrenous inflammation. It is generally not difficult to distinguish between a phthisical cavity and a dilated bronchus. The latter is not characterized by the broken irregular surface which usually exists in the former; its shape is generally more regular; and it is usually continuous with bronchial tubes. The surrounding lung-tissue has no tubercular infiltration.

SMIA). Contraction of the bronchia largely influences the pulmonary vessels, and considerable obstruction of the pulmonary circulation is the result. The vessels become gorged, and sometimes the lungs oedematous. If the emphysema be extensive, we may in time expect dilatation of the right side of the heart and marked prominence of the veins of the breast and neck, and the effects may be carried so far as to cause oedema of the lower extremities with albuminous urine, as the writer witnessed in a case where the latter symptoms disappeared on the subsidence of the asthma.

PATHOLOGY.—Patients rarely, if ever, die of spasmodic asthma, though death may ensue from some of its complications and sequelæ; and the disease being a functional one, cannot be said to have any morbid anatomy. The onset and departure of the attack, and the ever-changing physical signs, led Laennec to think that, whatever obstruction in the bronchial tubes caused the phenomena, must be of a spasmodic and transitory nature. He therefore concluded that asthma was due to a spasm of the bronchial muscles which had been described by Reissner. Laennec also showed that an asthmatic sufferer could sometimes, after holding his breath, actually breathe naturally for one or two respirations, thus clearly demonstrating that the spasm was capable of momentary relaxation. Other theories were put forward, and doubt was thrown on the existence of muscular fibres in the bronchi, until Dr. C. J. B. Williams proved their existence by his experiments on the lungs of oxen, dogs, rabbits, and other animals, when he caused contraction of the trachea and bronchial tubes by the application of electrical, chemical, and mechanical stimuli. The muscular coat was shown to be more abundant in the smaller tubes than in the larger, the former contracting sufficiently to entirely obliterate their passages. In asthma, excitation of the muscle probably takes place through the anterior and posterior pulmonary plexus, which are made up of branches from the pneumogastric, recurrent laryngeal, the spinal nerves, and the ganglia of the sympathetic, thus giving the bronchial tubes a very wide area of connections. The branches of the pulmonary plexus form a network round the bronchial tubes, and contain some minute ganglia. When the cause is direct, as dust of any kind or climatic influence, the spasm may be induced by reflex action through these small ganglia, or through the pulmonary plexus, though it soon extends deeper into the nervous system, involving the pneumogastrics and causing a motor effect on the thoracic muscles through the upper cervical, phrenic, and dorsal nerves. Where emotion, fright, or laughter starts the fit, the irritation is centric, and causes a motor effect on the pulmonary plexus through the pneumogastrics. Where, again, indigestion excites it, the sensation passes through the gastric branches of the pneumogastric, and is reflected by the motor filaments of the pulmonary plexus. Lastly, where gout, syphilis, skin-disease, and heredity are the excitants, we may regard the blood itself as causing the local irritation. Spasmodic asthma may, therefore, be considered as a neurosis of the pul-

monary branches of the plexus of that name similar to other neuroses, as hemicrania and sciatica, and giving rise through the motor nerves of the plexus to spasm of the bronchial muscle.

DIAGNOSIS.—Asthma is distinguished from *bronchitis* by the fugitive physical signs; by the spasmodic character of the dyspnoea; and by the scant expectoration. The breathing in bronchitis, if at all difficult, is hurried; if asthma it is slow, wheezy, and prolonged; this feature also contrasting strongly with the gasping, panting dyspnoea generally accompanying pneumonia, pleurisy, and some forms of heart-disease. From *croup* it is recognised partly, but not entirely, by the age of the patient; and partly by the character of the dyspnoea, which in *croup* is *inspiratory*, whereas in asthma it is mainly *expiratory*. This characteristic also distinguishes asthma from *spasm of the glottis* and the various forms of *laryngeal dyspnoea*. The diagnosis from *emphysema*, which is so often mixed up with spasmodic asthma, is founded chiefly on the paroxysmal character and violence of the asthmatic dyspnoea; and on the complete freedom of the intervals, the dyspnoea of emphysema being more or less permanent.

Aneurism of the aorta and other *mediastinal tumours* often give rise to symptoms so exactly simulating spasmodic asthma as to make the diagnosis difficult, and this is to be accounted for by these tumours pressing on the pneumogastric and its branches, and thus inducing an asthmatic spasm. These cases are, as a rule, however, accompanied by a certain amount of stridor arising from laryngeal spasm, not present in asthma, and this symptom is often of great diagnostic value in obscure cases. As the tumour enlarges, it causes greater pressure on the lungs, trachea, œsophagus, sympathetic ganglia, or other structures, and produces shrill cough, dysphagia, difficulty of inspiration, pain in the chest, impulse in the thoracic wall and other noted aneurismal symptoms. Moreover, certain physical signs become evident, *e.g.* dulness over the first portion of sternum or to the right of it, or between the scapulae; tubular sounds; and bronchophony close to the sternum, or above one or both scapulae; or some form of bruit or murmur in the course of the aorta. These and other symptoms and signs contrast sufficiently with those of spasmodic asthma, to make the diagnosis from developed aneurism comparatively easy.

In some cases of *renal disease* a form of dyspnoea appears, which is occasionally marked by paroxysmal features, and has been mistaken for spasmodic asthma. Renal dyspnoea differs, however, as a rule, in being more continuous, and in having for its origin oedema of the lung rather than bronchial spasm.

PROGNOSIS.—The question of recovery in cases of asthma depends to a certain extent,—

Firstly, on the possibility of the removal of the exciting cause;

Secondly, on the age of the patient;

Thirdly, on whether the attacks increase or not in frequency;

Fourthly, on the condition of the lungs and breathing in the intervals.

If the patient be young (say, under fifteen), the

chest well-formed, the attacks tending to diminish in frequency and intensity, and the lungs free in the intervals, a most hopeful prognosis can be given. If, on the other hand, the patient be middle-aged, the attacks increasing in number and severity, and the breath more or less short in the intervals, we may conclude that there exists a considerable amount of permanent emphysema, which renders the prognosis of an unfavourable character. In every instance the detection and removal of the exciting cause or causes, as the case may be, exercise a chief influence over the prognosis.

TREATMENT.—The principal difficulty in the treatment of asthma lies in clearly ascertaining the origin of the irritation, and when this is discovered two great principles should guide us, namely, first, to avoid or remove the exciting cause; secondly, to allay and prevent the spasm.

Many of the cases arising from direct causes, as from dust, chemical vapours, &c., are cured by simple avoidance of the exciting cause. Where bronchial inflammation induces the spasm, the inflammation must be subdued by salines and expectorants, combined with some anti-spasmodic, as belladonna, henbane, or stramonium. In more chronic instances, where some thickening of the walls of the larger bronchi and enlargement of the bronchial glands exist, iodide of potassium in doses of grs. iii. to x., has been found beneficial when persisted in for long periods. Where the attacks depend on a morbid state of blood, as that associated with gonit, syphilis, renal disease, or connected with skin-disease treatment must be directed to the condition of this fluid, which, if improved, will no longer induce bronchial spasm. Arsenic proves of signal service in asthma co-existing with eczema, psoriasis, and other skin-affections.

Where heredity is the predisposing cause, the origin of the disease lies generally in defective development of the frame or of the lung-structure of the patient: for such persons gymnastic exercises, swinging on the trapeze, and other means of expanding the upper part of the chest and correcting the asthmatic stoop are to be employed, combined with cold sponging and as much outdoor life as possible, with walking and riding in moderation.* The tendency to catarrh is thus lessened, and the frame of the patient developed and fortified. In a large number of cases, as, for instance, those arising from climatic influences, we have to treat a simple neurosis, and to allay the spasm either by climatic or by medicinal means, of which the former is often the more important, and, owing to the leading part played by the idiosyncrasy of the patient, generally the most difficult. In obstinate cases the doctrine of contrasts appears the only safe one. Where the disease has been contracted in a moist climate, a dry one must be tried; if in an inland district, the seaside must be resorted to; but for by far the majority of asthmatics the atmosphere of large towns is suitable, and the smokier the air and the closer the streets the more good do the sufferers appear to receive. London, Glasgow, Birmingham, and Bristol are all favourable resorts for cases of neurotic asthma: and the points of difference

between their atmospheres and that of the country consist, (1) in dryness; (2) in deficiency of oxygen; and (3) in excess of carbonic acid and carbon: all of which peculiarities appear to exercise a sedative effect on the neurosis. Dump, whether of soil or atmosphere, is usually found to be hurtful, and is one of the chief exciting causes of asthma.

The medicines most useful in asthma are anti-spasmodics, either stimulant or sedative: the former, including alcohol, strong coffee, spiritus aethers, and nitrite of amyl, will prove more efficacious where emphysema is present; the latter comprise stramonium, belladonna, Indian hemp, lobelia, tatusia, tobacco, opium with its salts, and many other drugs. These may be taken internally in the form of extracts or tinctures; or smoked in pipes or as cigarettes; or inhaled as vapour diffused through the room by burning papers or pastilles containing them. A popular and often reliable remedy is the vapour arising from the combustion of nitre-paper. In the severest attacks the patient can neither smoke nor swallow, and in this difficulty of introducing medicines into his system we find the hypodermic injection of atropine, morphia, and chloral proves effectual; but if emphysema be present, or if the pulse be weak, it must not be attempted. Chloroform often acts like a charm in the worst case, and after inhaling 20 to 60 minims the patient will gain the sleep which has been denied to him for hours, or even days; but the effect is generally transitory, and the use of the remedy not free from risk. Ether is safer, but not so effective. Chloral-hydrate in doses of 15 to 20 grs., repeated every four hours until the spasm subsides, has produced not only temporary, but even permanent good in a large number of asthmatic cases, and if watched, may be persisted in for some time. In the writer's hands it has proved the most successful remedy. In the use of anti-spasmodics we must avoid judging the effects of one from the failure of another of the same class; but in difficult cases we must try each in succession—for it often happens that the successful remedy is only arrived at after repeated trials.

Certain mineral waters, and especially those of Mont Dore and the Pyrenean sulphur springs of Eaux Bonnes, Eaux Chaudes and Cauterets, are reputed to exercise a beneficial influence over asthma, but they have not been successful in the writer's experience, and it is more probable that they relieve by reducing the catarrhal symptoms than that they either allay the spasm or prevent its recurrence.

Compressed air baths at pressures varying from 3½ to 7 inches of mercury, and lasting two hours, have afforded considerable relief. See AIR, Therapeutics of.

The dietetic treatment varies in individual cases, but as a rule asthmatics should dine early, and for the rest of the day limit themselves to liquid food, such as beef-tea, soups, and milk, combined with such an amount of stimulant as may be necessary, thus avoiding any distension of the stomach and intestines before retiring to rest. The diet should consist of brown bread, toast, and biscuits—excess of starch in any form being studiously avoided—a fair supply of plainly

cooked meat, fish or poultry, and a limited amount of vegetables and fruit, care being taken to select only the most digestible of each class.

C. THEODORE WILLIAMS.

ASTIGMATISM — ASTIGMISM (ἀ, priv., and *stigma*, a spot or point).—Want of symmetry in the anterior refracting surfaces of the eyeball, in consequence of which rays of light proceeding from a point cannot be brought to a focus upon the retina as a point, but only as a diffused spot. See VISION, Disorders of.

ASTRINGENTS.—DEFINITION.—Medicines which cause the contraction of tissues.

ENUMERATION.—The chief astringents are Nitrate of Silver; Sulphate of Copper; Sulphate of Zinc; Acetate of Lead; Perchloride of Iron; Alum; Tannic and Gallic acids, and vegetable substances containing them, such as Oak Bark, Galls, Kino, and Catechu; and Dilute Mineral Acids. Some authors also include in this class of remedial agents such articles as Ergot of Rye, which contracts the blood-vessels and lessens hæmorrhage after it has been absorbed into the blood, although it has no local astringent action.

ACTION.—With the exception of gallic acid, the substances already mentioned coagulate or precipitate albumin. Dilute mineral acids do not coagulate albumin, but precipitate many albuminous bodies from the alkaline fluids by which they are held in solution. When applied to a surface from which the epidermis has been removed, the other astringents combine with the albuminous juices which moisten this surface, as well as with the tissues themselves, and form a pellicle more or less thick and dense, which in some measure protects the structures beneath it from external irritation, at the same time that they cause the structures themselves to become smaller and more dense. On a mucous membrane they have a similar action, and they lessen its secretion. It was formerly supposed that their action was partly due to their causing the blood-vessels going to a part of the body to contract, thus lessening the supply of fluid to it; as well as to their effect on the tissues themselves. But experiment has shown that, while nitrate of silver and acetate of lead possess this power, perchloride of iron and alum do not, and that tannic and gallic acids actually dilate the vessels. The astringent action of these latter drugs must therefore be exerted upon the tissues.

Uses.—Astringents may be employed locally in various forms. In the solid form, as a powder, or in various preparations such as lotions, ointments, plasters, glycerines, &c., they are applied, especially the metallic astringents, to wounds and ulcers for the purpose of reducing the size and increasing the firmness of exuberant granulations, as well as of protecting the surface by forming a pellicle over it. They are used to lessen congestion and diminish the secretion of the various mucous membranes—as a lotion to the eye and mouth; as a gargle or a spray to the throat; in the form of an injection to the nose, urethra, and vagina; and as a suppository to the rectum. Administered internally several astringents have a powerful effect in checking diarrhoea, and certain of them

may have a local action upon the stomach and intestines.

The remote action of such astringents as acetate of lead and gallic acid, when absorbed into the blood, in lessening hæmorrhage, is made available in the treatment of hæmoptysis, hæmatemesis, hæmaturia, and loss of blood from other parts of the body.

T. LAUDER BRUNTON.

ASTURIAN ROSE.—The rose or erythema of the Asturias; one of the numerous synonyms of Pellagra—*Mal de la rosa*; *Lepra Asturiensis*; *Elephantiasis Asturiensis*. See PELLAGRA.

ATAVISM (*atavus*, a grand'father) signifies the inheritance of a disease or constitutional peculiarity from a generation antecedent to that immediately preceding.

ATAXIA
ATAXIO } (ἀ, priv., and *taxis*, order).—

Terms which originally meant any irregularity or disorder, but are now specially applied to irregularity of associated or co-ordinated muscular movements. The noun is frequently used as synonymous with the disease known as Locomotor Ataxy. See LOCOMOTOR ATAXY.

ATELECTASIS (*ἀτελής*, imperfect, and *ektasis*, expansion).—Absence or imperfection of the expansion of the pulmonary alveoli which normally takes place at birth, the lungs thus remaining more or less in their fetal condition. See LUNGS, Collapse of.

ATHEROMA. See ARTERIES, Diseases of.

ATHETOSIS (*ἄθετος*, without fixed position).—DEFINITION.—A name given by Dr. Hammond of New York to a condition in which the hand and foot are in continual slow irregular movement, and cannot be retained in any position in which they may be placed.

DESCRIPTION.—The special character of the movements in athetosis is that they are slow and deliberate. They usually affect the arm and leg on one side only. Voluntary power is retained, but is interfered with by the slow spasm. The fingers are irregularly flexed and extended: at one moment they spread wide apart, the thumb being over-stretched, thereafter first one, then another is bent in to the palm, and again extended. The movement can be arrested for a moment in certain positions by the will, but is renewed with increased force. The foot is usually inverted; the toes being flexed or extended, but in less constant movement. The spasm may cause pain. The muscles sometimes become hypertrophied. The movements in some cases cease during sleep, in others they do not. Sensation is often, but not always impaired. The onset of this condition is usually sudden, and in some cases with a convulsion. The subjects have been generally in middle life.

Athetosis differs from the spastic contracture so common after hemiplegia in children in the slowness and spontaneity of the movements; but the two conditions are probably very closely allied. It cannot be regarded as a distinct disease. Typical athetosis may succeed hemiplegia.

PATHOLOGY.—It is probable that, as Dr

Hammond suggests, the seat of the mischief in athetosis is the corpus striatum or optic thalamus. The sudden onset of the disease, and the slight affection of sensation, render it probable that a lesion damaging, but not destroying, a portion of one of these nuclei, leads to a perverted action of the nerve-cells, so that abnormal motor impulses are originated, and those transmitted from above disturbed—'irradiated' (Nothnagel). Charcot believes that all post-hemiplegic choreoid movements depend on the implication of fibres outside the optic thalamus. In a case of simple ataxy after hemiplegia—an analogous condition,—the writer has found a cicatricial sclerosis extending across the optic thalamus, and probably left by a patch of softening.

PROGNOSIS.—This is unfavourable, but the slighter cases improve and may even approximately recover.

TREATMENT.—Nervine tonics and sedatives are the remedies chiefly indicated. Of the former arsenic, and of the latter Indian hemp, do most good; bromides are also useful. The continuous current is perhaps the agent which affords most distinct relief. In one well-marked case under the writer's care the spontaneous movements ceased entirely after some months' galvanisation. The positive pole may be placed on the spine or brachial plexus, the negative on the muscles involved. The action of the continuous current is probably in part direct, in part reflex, lessening by the peripheral impression the over-action of the centre, as do some other peripheral impressions.

W. R. GOWERS.

ATONIC } (â, priv., and *tênos*, tone).—
ATONY }

Terms implying want of tone, power, or vigour, and associated either with such a condition of the system generally, or of particular organs, especially those which are contractile.

ATRESIA (â, priv., and *trêmô*, I pierce).—Absence of a natural opening or passage, whether congenital or caused by disease.

ATROPHY, GENERAL.—**SYNON.**: **Marasmus.**

DEFINITION.—Atrophy means, etymologically, simply want of nourishment (â, priv., and *τροφή*, nourishment), but the term is commonly applied to the condition resulting from want of nourishment, namely, wasting or diminution in bulk and substance, even though this may have been produced by some other cause, and even though the supply of nutritive material may have been abundant. *General atrophy* is used to denote wasting in which the whole body participates. All acute diseases, if severe, are accompanied by emaciation, for at such times nutrition is temporarily interfered with. The use of the word 'atrophy' is, however, confined, as a rule, to cases where the interference with nutrition has been gradual, and the loss of flesh consequently slow.

ETIOLOGY.—Atrophy is common enough at all periods of life. In infants and children it is due, in the majority of cases, to chronic functional derangements which interfere with the digestion and elaboration of food. Less frequently it is a

consequence of organic disease. In adults general atrophy seldom results from any other cause than organic disease, and functional disorder as a cause of serious wasting is the exception. In old age atrophy is a common consequence of the degenerations of tissue which accompany the decline of life. The interference with nutrition may, however, be aggravated by the presence of disease.

In *infants under twelve months old* there are four principal causes to which chronic wasting can usually be referred, namely, unsuitable food, chronic vomiting (gastric catarrh); chronic diarrhoea (intestinal catarrh); and inherited syphilis. Bad feeding, by setting up a chronic catarrhal condition of the stomach and bowels, is a frequent cause of both vomiting and diarrhoea, but it may produce atrophy without either of these symptoms. When an infant is fed, for instance, with large quantities of farinaceous matter—a form of food which is alike indigestible and innutritious—a very small part only can enter as nutriment into the system. The remainder passes down the alimentary canal, and is ejected at rare intervals in an offensive putty-like mass or in hard roundish lumps. The child, therefore, although overladen with food, is really under-nourished, and loses flesh as long as such a diet is persisted in. If, as often happens, diarrhoea or vomiting be set up by the irritation to which the digestive organs are subjected, wasting is more rapid and the danger of the case is increased. Any form of bad feeding, and not only excess of farinaceous matter, will produce this result. Wasting, indeed, will be found in every case where the food selected is unfitted for the child, and thus it is not unfrequently seen in infants who are fed upon milk and water alone. The casein of cow's milk is difficult of digestion by many infants on account of its tendency to coagulate into a large firm clot like a lump of cheese. In this respect it differs from the curd of human milk, which forms light small flocculent coagula, and is digested without difficulty. Special preparation is therefore generally required to render cow's milk a suitable diet for a young child.

It is not only, however, unsuitable food which is a cause of atrophy in infants. Catarrh of the stomach and bowels may be present, although the feeding is in all respects satisfactory. Infants are excessively sensitive to chills, and catarrh of their delicate digestive organs is easily excited. Now, catarrh of a mucous membrane is always accompanied by an increased flow of mucus, and this alkaline secretion in excess acts as a ferment and sets up decomposition of food. A sub-acute gastric catarrh from this cause is not rarely seen in new-born infants, who thus are rendered for the time incapable of digesting even their mother's milk. In such cases the fault is usually attributed to the milk, which is said to be unsuited to the child; and the mother is compelled, much against her will, to wean her baby and feed it in a different way. So long as the catarrh continues, however, no food appears to agree, and the child often after a time dies exhausted.

Between one and three years atrophy is commonly associated with rickets. In these cases

the wasting is noted chiefly about the chest and limbs, for the belly is large and swollen from sterculent accumulation. At this age children are still liable to waste from catarrh of the stomach and bowels: indeed, rickets is itself often complicated by such derangements. Cancer of the internal organs is also sometimes found at this time of life, and is attended with extreme emaciation.

After the age of three years caseous enlargement of the mesenteric glands becomes a cause of wasting.

After the fifth or sixth year chronic pulmonary phthisis begins to appear. Cases of heart-disease as a result of acute rheumatism are also more frequently seen. Diabetes, too, is sometimes met with. All these diseases may produce much interference with nutrition.

From the time that the child begins to take other food than that furnished by his mother's breast, he is liable to worms in the alimentary canal. The presence of worms is frequently accompanied by loss of flesh, not, perhaps, so much on account of the parasites themselves, as on account of the derangement of the digestive organs which is associated with them. Emaciation due to this cause may sometimes be extreme.

In the adult atrophy is rarely the result of mere functional derangement, but is almost invariably a sign of serious organic disease. All chronic ailments are not, however, accompanied by marked wasting. Purely local diseases lead to little loss of flesh unless they affect some part of the digestive apparatus, or of the glandular system which is concerned in the elaboration of nutritive material; or otherwise directly influence the processes of nutrition. Thus, emaciation quickly results from gastric ulcer or chronic dysentery, but chronic pneumonic phthisis may produce little diminution in weight if there is no pyrexia, and if the case is not complicated by diarrhoea or profuse expectoration. The most marked atrophy is produced by the so-called constitutional diseases, such as cancer and syphilis in the third stage, by those which set up a persistent drain upon the system, such as severe albuminuria, chronic hæmorrhages, and long-continued suppurations; or by those which directly impede the passage of nutritive material into the blood: and in the latter class of diseases, influences which act directly upon the thoracic duct, such as obstruction to its passage from pressure by aneurism and other tumours, must not be overlooked. There is a form of atrophy sometimes seen in hysterical females, depending upon disordered innervation, in which the most extreme emaciation may be reached. Such cases are marked by a dislike to food which may amount to absolute loathing.

SYMPTOMS.—The symptoms of general atrophy are loss of flesh, loss of colour, and loss of strength, combined with other special phenomena arising from the particular disorder to which the impairment of nutrition is due.

ANATOMICAL CHARACTERS.—The most marked post-mortem appearance in this condition is diminution or loss of fat, especially of the subcutaneous adipose tissue; and this is accompanied by wasting of the tissues and organs

generally. The histological elements are reduced in size without undergoing, as a rule, actual numerical diminution. With the atrophy is often associated a certain amount of fatty degeneration.

TREATMENT.—The treatment of general atrophy consists in removing, if possible, the impediment to efficient nutrition. In the case of a child the diet must be selected with care. Excess of farinaceous food is to be avoided, and c.w's milk can be diluted, if necessary, by admixture with thin barley water. Any gastric or intestinal derangement must be at once remedied, plenty of fresh air should be obtained, and perfect cleanliness strictly enjoined. In an adult the disease which is the cause of the malnutrition must be sought for and submitted to treatment. Efforts should be made on the one hand to arrest any drain upon the system, and, on the other hand, by a judicious arrangement of the dietary, and by attention to the eliminatory organs, to remove all obstacles to the entrance of nourishment. Even in cases of organic and incurable disease much benefit may often be derived from due observance of physiological laws.

EUSTACE SMITH.

ATROPHY, LOCAL.—This condition signifies atrophy of a part of the body, which may be apparently congenital, or may be produced by various causes acting during life. It will be convenient to consider local atrophy according to the several forms which are met with.

Congenital Atrophy is that condition in which some part of the body never reaches its full standard of size. It is more correctly denominated *arrested growth* or *congenital smallness*. When the whole of one side of the body is thus affected, a marked and permanent disproportion between the two sides results. This *hemiatrophy* is, in theory, difficult to distinguish from hypertrophy of the opposite side, but mostly the paralytic or enfeebled state of the atrophic side shows it to be abnormal. The limbs are most strikingly implicated, while the corresponding side of the face and head is sometimes similarly, sometimes conversely affected. In many cases atrophy of the opposite half of the cerebrum was found on post-mortem examination. The same condition may be partial—*hemiatrophia partialis*—and it then chiefly affects the face, or some part of the territory of the fifth cranial nerve. These conditions must be ascribed to some perversion of innervation occurring during development. Other congenital atrophies, *local* but not *hemiatrophic*, are more probably referred to obstruction of blood-vessels during the same process. The defective development of the brain in cretinism has been attributed to the pressure of an enlarged thyroid upon the carotid arteries.

Physiological Atrophies.—These form a distinct class, where atrophy of a part of the body takes place in the ordinary course of development. Such are the wasting of the thymus gland in early life, of the mammae and sexual organs after middle age. Most commonly the atrophy is here closely connected either with the involution or perhaps the development of some correlated organ; but it is not possible

to any what the nature of this connection is, whether one of nutrition or of innervation.

Acquired Atrophies.—The conditions thus distinguished possess most interest for the practical physician. Wasting of any part of the body during life, when not physiological, usually depends either upon some interference with the blood-supply, or some disturbance of innervation; but to these must be added, in the case of organs which have an active and continuous function, disease or over-stimulation. Deficient blood-supply, which causes atrophy, may be produced by the obstruction of a nutrient artery, especially if it be gradual, since sudden blocking will produce more complicated phenomena. Constant pressure is a cause of atrophy, because it interferes both with the blood supply, and with the vital actions of the tissue-elements. Intermittent pressure, on the other hand, by causing hyperemia, is more likely to lead to hypertrophy. Moreover, inadequate renewal of blood, that is, filling of the vessels, even to excess, with venous blood, or venous engorgement, though at first it may cause enlargement, mostly leads to atrophy in the end; as is seen in the granular induration of liver and kidneys caused by disease of the heart obstructing the circulation. Many forms of atrophy in old age are clearly dependent upon senile obstruction of the arteries, for example, that of the skin, spleen and kidneys. The instances of atrophy from disturbed innervation are less easy to discriminate, except where there is actual paralysis. In two distinct diseases, however, *progressive muscular atrophy* and *infantile or essential paralysis*, loss of power in the muscles is followed by a remarkable wasting, far more rapid than that which results from disease alone. Division of the nerve of a limb produces rapid wasting of the muscles no longer used, and this is accompanied in the end by some diminution in the size of the bones and accessory parts. Local atrophy of the skin is sometimes seen in regions limited by the distribution of a nerve, especially some branch of the fifth, and more extensive atrophy of one side of the face or head, equally marked out by nervous distribution, and resembling some cases of congenital atrophy, has also been, though very rarely, observed. These facts raise the interesting question whether there are 'trophic nerves.' Without discussing this question, it may be pointed out that the nerves which delineate an atrophic region are always motor or mixed branches, never solely sensory.

Disease produces atrophy only in organs whose functions are active and constant, such as nerves and muscles. Nervous tissue wastes constantly, and sometimes rapidly when currents cease to traverse it. This is seen not only in the nerves of paralyzed limbs, but even in the nerve-centres, where any interruption of the nervous channels, either above in the cerebrum, or below in the nerve-trunks, is followed by degeneration, ending in atrophy, of the whole nervous tract leading from the cerebral cortex to the peripheral termination—so called *secondary degeneration* of the cord. In muscular tissue the wasting is almost as constant, but hysterical paralyses make an exception, the helpless limbs preserving their nutrition in a surprising manner. In organs whose functions

are intermittent or periodic, disease does not appear necessarily to produce atrophy, as is seen in the ovaries, testicles, and mammae.

That excessive stimulation or over-work may produce atrophy is seen in degenerative diseases of the nerve-centres arising from undue mental activity; and of the sexual organs from excessive indulgence.

Unexplained Atrophies.—Cases of local atrophy occur of which it is impossible to give any satisfactory explanation. Such are the conditions known as linear atrophy of the skin; some remarkable cases of atrophy of bone, especially of the skull (*fragilitas ossium*), and of some parts of the cerebrum. We may have to attribute to changes of the latter class just mentioned, certain peripheral atrophies, without being able to account for the original lesion.

It is possible that deficiency of special kinds of food may lead to atrophy of special organs—thus deficiency of lime may make the bones soft, and deficiency of iron arrest the development of blood-corpuscles; but even these familiar instances must be accepted with a little reserve. In the same way it is still doubtful whether any special drugs, such as iodine, can produce atrophy of special glands.

PATHOLOGY.—Wasting may occur simply, or as a consequence of change of substance, or from the intrusion of some new material; in other words, there may be *simple atrophy*, atrophy from *degeneration*, or atrophy by *substitution*. The first is probably rare; generally some change of substance occurs. The most frequent degenerative process is fatty degeneration; the albuminous substance being converted into or replaced by fat, which, if afterwards absorbed, leaves a void. Organs thus affected may be apparently enlarged, though the original substance is wasted. Atrophy from substitution is seen when the connective tissue of an organ, for instance, increases, compressing and destroying the other tissue-elements, and these not being renewed when the newly-formed connective-tissue is absorbed, the whole organ is diminished in bulk. This is seen in all the changes called cirrhosis or fibroid degeneration, as in cirrhosis of the liver and kidneys.

TREATMENT. No general rules can be laid down for treating all cases of local atrophy. Where the blood-supply is deficient, we have rarely any means of supplementing it; where innervation is at fault, it is seldom under our control. In general, harm rather than good results from any attempt to attract blood by artificial irritation. In the case, however, of atrophy from disease of the nerve-muscular system, a line of treatment, and more especially of prophylaxis, is very clearly indicated; that is, to keep the muscles in exercise by artificial means, particularly by electricity, or by the processes of friction and kneading, known as *passive motion*. In this way so much of the atrophy as is due simply to disuse may be checked for the future, and even the past loss reinstated. We shall, moreover, never do harm by attempting to supply some special kind of food which appears to be deficient, as iron for the blood and phosphorus for the bones or nervous system.

J. F. PAYNE.

AUDITORY NERVE. Diseases of. See EAR, Diseases of; and HEARING, Disorders of.

AURA (*αἶσα*, a breeze).—A peculiar sensation, subjective in origin, immediately preceding an epileptic or hysterical convulsion, and named respectively *Aura Epileptica* and *Aura Hysterica*. The word was originally adopted because the sensation is often described as that of the passage of cold air or light vapour from the trunk or extremities to the head; but it has been extended so as to include any phenomenon, whether sensory or motor, that ushers in a fit of epilepsy or of hysteria.

AURAL DISEASES. See EAR, Diseases of.

AUSCULTATION (*ausculto*, I listen).—A method of physical examination, which consists in listening over various parts of the body, either by the direct application of the ear (*immediate auscultation*), or by the aid of special instruments (*mediate auscultation*), for the purpose of studying certain sounds produced in health and disease. See PHYSICAL EXAMINATION.

AUSCULTATORY PERCUSSION.—A method of physical examination in which the sounds elicited by percussion are studied by means of auscultation. See PHYSICAL EXAMINATION.

AUSTRALIA. See APPENDIX.

AUTOPHONIA (*αὐτός*, itself, and *φωνή*, the voice).—A physical sign obtained by studying the modifications of the resonance of the observer's own voice during auscultation. See PHYSICAL EXAMINATION.

AUTOPSY. See NECROPSY.

AZORES, St. Michael's.—Warm, very moist, equable climate. Mean winter temperature 58° F. Prevailing winds N. and E. See CLIMATE, Treatment of Disease by.

AZOTURIA.—A condition of the urine in which there exists an absolute and relative excess of urea, without accompanying pyrexia. See URINE, Morbid Conditions of.

B

BACILLUS (from *bacillum*, a little staff) is the name now given to certain filiform *Bacteria* which have assumed much importance of late, principally because of their constant presence in the blood and tissues in splenic fever and malignant pustule. See LEPTOTHRIX, and BACTERIA; also PUSTULE, MALIGNANT; and BACILLI in APPENDIX.

BACTERIA (*βακτήριον*, a rod) are some of the lowest known forms of life. They most frequently exist as minute rod-like bodies, about $\frac{1}{1000}$ inch in length, with a slight median constriction. They may be larger or smaller than this, and may present minor variations in form. They swarm in all putrefying solutions and mixtures of organic matter, and in many fermenting fluids in which the chemical changes are not accompanied by an emission of stinking gases. In fluids belonging to the latter category, the typical *Torula* or yeast-cell may be met with, as well as organic forms strictly intermediate between it and the typical Bacterium. From a chemical point of view, it is admitted that no absolute line of demarcation can be drawn between the intimately related processes of *putrefaction* and *fermentation*; whilst from a biological point of view we are similarly unable to erect any impassable barriers between the organic forms which are found as part of the products of change in putrefying and fermenting fluids respectively. It is unquestionably true that typical *Bacteria* are most frequently met with in putrefying fluids; whilst, on the other hand, typical *Torulae* are only present in some fermenting fluids. But the rather long rod-like bodies, which have been hitherto named *Vibriones*, and the still longer filaments mostly known as *Leptothrix* (see LEPTOTHRIX), are unquestionably capable of being derived from ordinary *Bacteria* in certain media.

In the most highly putrescent fluids *Bacteria*

are usually found to be very small, because, though the total bulk of living things rapidly augments in such fluids, the individual units (in consequence of the frequency with which a process of fission takes place) do not increase in size. In less putrescent fluids, however, where the chemical changes constituting the putrefactive process take place more slowly, the living forms also appear and grow with less rapidity; and owing to the co-existence of a lower frequency of fission or spontaneous division amongst such individual living units, they often attain a larger size. They then appear, according to their length, either as *Vibriones* or as *Leptothrix* filaments. These are plain, jointed, or mutilated, according as partial segmentation is absent, has taken place rarely, or has occurred so rapidly as to give what would have been a plain filament the appearance of a string of beads.

Concerning the question of the precise relation of organisms to the processes of putrefaction and fermentation, opposite opinions are at present held. Believers in Pasteur's germ-theory maintain that they are invariably the initiators of these chemical processes; whilst those who reject this theory, as being too exclusive, contend that putrefaction and fermentation may be initiated in the absence of *Bacteria* and their germs. Those holding the former view believe that *Bacteria* are only capable of being derived from pre-existing organisms of like kinds; whilst those who reject it contend that particles of living matter, which develop into *Bacteria*, may be generated from the organic compounds dissolved in fermentable fluids, and that such particles of living matter are, in fact, just as much products of the fermentative process and of the fluid in which it occurs, as are the gases simultaneously generated therefrom. According to this view, these lowest living units bridge the gap hitherto held to exist between living

and so-called dead matter, and afford an illustration of the natural independent origin of chemical compounds so complex and endowed with such attributes as to win for them the name of 'vital' compounds (See *Proceedings of the Royal Society*, No. 172, 1876, pp. 149-166.)

Pasteur's 'Vital theory' of fermentation is one of great importance both to chemists and biologists, and it also forces itself upon the attention of medical men, as the parent of another doctrine which has of late assumed great prominence in relation to the science of medicine—the doctrine, namely, that lower organisms allied to those met with in putrefying and fermenting media are causally related to certain morbid processes with which they either do, or are said to coexist. Bacteria and their allies are as uniformly coexistent with a few general diseases and certain local morbid processes as they are with putrefactions and fermentations, so that the same general question as to the precise significance of this coexistence again presses for solution. Are the organic forms associated with such morbid processes the sole causes or incitors of these processes? or are they consequences (i.e. concomitant products) of pathological processes which have been initiated in their absence? The former view is warmly supported by many who regard bacteria and allied organic forms as the contagious elements of such communicable diseases, and many of these same pathologists, resting upon analogy, wish to extend their theory, so as to make it applicable to many other communicable diseases with which organic forms have not as yet been shown to be correlative.

Thus, just as certain chemists hold that Bacteria and allied forms are the causes of all fermentations and putrefactions, so certain pathologists either do actually, or are inclined to maintain that Bacteria and allied organisms of common or of special kinds are the causes of all communicable or contagious diseases. According to such chemists all *ferments* are living organisms; and according to such pathologists all *contagia* are allied living organisms.

The coexistence of organisms is one which obtains for almost all fermentations, but only for a few of the communicable diseases, so that any argument deducible from such mere coexistence in favour of the causal relationship of the organisms, is much stronger in the case of fermentations than as regards diseases. Yet, in spite of the almost universal coexistence of organisms with fermentations, it is still necessary for us to ask whether they appear as causes or as effects of these phenomena. From this it may be judged how little the more limited 'facts of coexistence' should be allowed to influence our opinion on the derivative question of the relation of the lower organisms to disease. At least one of the reputed instances in which this coexistence of organisms has been dwelt upon, as showing that they are the causes of the morbid phenomena with which they are associated, has of late been dissipated, since in the case of the small-pox of sheep (*variola ovina*) the alleged organisms are now admitted to have no existence—certain appearances pro-

duced in the tissues by preservative media having been mistaken for organisms which have been elaborately described and figured. (See *Proceedings of the Royal Society*, No. 172, 1876, p. 140.) But even if all the alleged cases of coexistence of organisms with morbid processes were real, and if future investigations should show that such facts are more numerous than are at present imagined, still the multiplication of this evidence to any extent will never help us (any more than it has done in the case of fermentations) to solve the real question—whether such morbid processes are only caused and propagated by organisms, or whether they may at times come into existence independently?

The vital or germ-theory of fermentation would be broken down and become untenable whenever it is shown that fermentation can originate independently of the Bacteria and their germs which appear as part of the process. Similarly, the germ-theory of disease would be refuted, if it could be shown that some of the morbid processes in question could originate in the absence of the living organisms which subsequently appear as part of the pathological products. The latter refutation, however, could never be made directly, since no living being could in any circumstance whatsoever be proved—in an experimental sense—to be beyond the possible reach of some of the alleged disease-germs. But inasmuch as this problem is, from its very nature, one which does not admit of experimental proof or disproof in the strict sense of the term, and because this germ-theory of disease is clearly a derivative doctrine from the germ theory of fermentation, it must stand or fall with the germ theory of fermentation, which, fortunately, is capable of experimental proof or disproof. The question of 'spontaneous generation' comes, therefore, to be inextricably mixed up with the question of the truth or falsity of the germ-theory of disease, so that the study of the latter to the neglect of the former can only end in the propagation of vagueness and uncertainty. The real question is not as to the extent or frequency of the coexistence of organisms with local or general diseases, but the much more important one as to the nature of their relation to such processes. If they act as invariable and sole causes, then their presence is a matter of the deepest interest and importance. If, on the other hand, the organisms are not causes but rather concomitant products, their presence from a purely medical point of view is of trifling importance. The study of their growth and development would in that case be important only as adding to our knowledge of the structural changes pertaining to the diseases in question. See *Transactions of the Pathological Society*, vol. xvi., and *Journal of the Linnean Society*, vol. xiv. See also the articles MICROCOCCI; PUSTULE, MALIGNANT; and ZYME.

BALANITIS = **BALANOPOTHITIS** (*Balanitis*, an acorn, and *pothitis*, the foreskin).—**SYNON.**: Bastard Clap; Blennorrhagia Balani; Inflammatory Phimosis.

DEFINITION.—Inflammation of the opposing surfaces of the glans and prepuce; sometimes acute—often gangrenous, and sometimes chronic. A purely local affection; frequently, but not necessarily, of venereal origin.

ÆTIOLOGY.—Balanitis is much less common than urethritis, being met with at the Lock Hospital in the proportion of one to twenty-four of the latter. It may be either primary; or consecutive to chancres, syphilitic eruptions, warts, accumulated smegma, variolous pustules, or gonorrhoea. When primary, the common *pre-disposing* cause is a long, narrow foreskin. Four other attributes two-thirds of the cases of balanitis to a long prepuce with insufficient cleansing; about one-third to irritation by chancres and gonorrhoeal pus; and a very few to other causes.

SYMPTOMS.—The symptoms of balanitis depend on the intensity and extent of the inflammation. In the simplest form there is heat and itching of the furrow, slight redness of that part, with a milky or yellowish secretion. When the inflammation is more severe and extended, swelling and pain are added, the other symptoms are more marked, and characteristic excoriations appear. They are irregular, shallow, never extending more deeply than the epithelium, but often coalescing into large raw chafings. An abundant yellowish-green matter of offensive odour bathes the surface. When the urine trickles over these excoriations there is severe smarting pain. If still further irritated, the foreskin swells enormously, is divided at the free border by deep creases, and can no longer be turned back. Aching, smarting, great tenderness, and painful erection, often accompanied by constitutional disturbance and fever, are present.

COMPLICATIONS.—The cellular tissue and the lymphatic ducts of the foreskin and sheath, or the lymphatic glands, may inflame to suppuration, to ulceration, and, in persons enfeebled by any cause, even to gangrene. Sloughing begins on the inner surface of the foreskin at the upper part; seldom to much extent, though the whole prepuce, except the frenum, may be lost, and when cicatrization sets in the organ appears circumcised. Paraphimosis is caused by imprudent retraction of a swollen foreskin. Warts keep up chronic posthitis of the furrow. Adhesions, usually at the corona and the furrow, may attach the prepuce completely to the glans. Thickening and phimosis are not uncommon after repeated attacks.

COURSE.—The duration of balanitis depends

on the anatomical condition of the parts. When remedies can be easily applied, it is not more than three or four days. With phimosis, the course is severe, and the duration is indefinite; even when limited to the furrow, posthitis is often obstinate.

DIAGNOSIS.—This is easy when the parts can be exposed. *Herpes* is distinguished from balanitis by small grouped round ulcers, limited to one or two points of the mucous surface, without general congestion. *Simple chancre* has well-defined undermined edges and a spongy surface. The *syphilitic sore* has the indurated base and enlarged lymphatic glands. When there is phimosis, the discharge may come from the urethra or from a chancre. If from the urethra, it can be usually seen escaping thence, and there is pain along the penis, with other signs of urethritis. A chancre under the foreskin is betrayed by a hard and tender point, and after a few days consecutive sores usually appear at the orifice of the prepuce.

PROGNOSIS in the primary form is always good. If the complaint is secondary or symptomatic, gangrene may result.

TREATMENT.—The chief indication is to keep the inflamed surfaces separate. After washing and thoroughly drying, the excoriations should be touched with a 10-grain solution of nitrate of silver, and a bit of dry lint laid on the glans before the foreskin is drawn forward. If there is phimosis, frequent injections of tepid water, and twice daily of a 5-grain solution of nitrate of silver must be thrown to the farthest part of the foreskin with a long-nozzled syringe. Leeches to the groins, and opium internally, as well as in injections, relieve pain. Acupuncture gives vent to simple oedema, but tend to accelerate gangrene with brawny tension and erysipelatous redness. Incisions, if needed should be free; one on each side, carried quite back to the furrow. The upper half of the foreskin can then be easily turned back, and the subsequent deformity is less than if the foreskin is divided at the dorsum. In paraphimosis, before replacing the swollen foreskin, the tension should be relieved by acupuncturo and astringent lotions, or by incisions if needed. **BRANKLEY HILL.**

BALDNESS.—**SYNON.**: Alopecia.

DESCRIPTION.—Baldness or loss of hair presents an extensive range of variation in degree, from moderate thinness of the hair, such as occurs in *Defluvium capillorum*, to complete baldness—*Alopecia calva* or *Calvities*, the latter not limited to the scalp alone, but involving eyebrows, eyelashes, beard, and every hair of the body. Instead, however, of being *general*, baldness may be *partial*, affecting more or less of the surface of the scalp for example, the summit and forehead in men, and the summit and occiput in women. One remarkable form of partial baldness has been denominated *Alopecia areata*, or simply *Area*, and as this was described by Celsus, it has likewise been called *Arva Celsi*. *Area* occurs suddenly, and is a mere falling-off of the hair over a space of circular figure; there may be one or more of such *Areae*, and sometimes *Area* is only the beginning of *Calvities*. *Area* is likewise occasionally met with in the whiskers and beard.

PATHOLOGY.—The pathology of Alopecia is a loss of nutritive power of the skin, sometimes progressive and consequent on advancing age, as in general baldness; and sometimes limited to a nerve-district of small extent, as in Area. This fact is very evident in the latter form, inasmuch as, conjoined with the sudden dropping-out of the hair, the integument is pale and thin, poorly nourished, somewhat anæsthetic, and thinner in the centre than at the circumference; while the hairs which remain at the periphery are altered in structure, clubbed and broken off.

ETIOLOGY.—The causes of Alopecia are exhausted nutritive power of the skin; nerve-paralysis in the case of Area; syphilis; and local injury. The Alopecia of syphilis follows the plan of distribution of its exanthem. Partial Alopecia may result from a blow; from the accidental tearing out of a lock of hair; from the sting of a bee; from nervous shock; or from other causes.

TREATMENT.—This consists in the restoration of nerve-power and nutritive power; and in local stimulation. The best applications for the latter purpose are the stimulating liniments of the British Pharmacopœia; *e.g.* liniment of ammonia, compound camphor liniment, and the liniments of chloroform and mustard; or the acetum cantharidis properly diluted for general Alopecia, or applied with a brush in its concentrated form for Area. In the treatment of the latter, ammonia, turpentine, and the compound tincture of iodine are likewise useful; while for syphilitic Alopecia the white precipitate ointment with camphor is the best local application, conjoined with an anti-syphilitic constitutional treatment.

BATHS.—Baths may be regarded as simple; and composite, medicated, or artificial. They may be used in the form of liquid, vapour, or air. We shall consider them under these heads in the following description:—

A. SIMPLE BATHS.—1. Simple Liquid Baths.

1. *The Cold Bath.*—By a cold bath is meant the immersion of the body in water below the temperature of 70°. Anything below 50° is considered a very cold bath. The first effect of

the bath is a sensation of cold amounting almost to shivering, with slight gasping for breath. If the bath is continued for more than two or three minutes, the temperature of the skin is diminished; and if it is protracted, the blood and the subjacent tissues lose a little heat, but this does not generally occur till after quitting the bath. If the cold is intense and prolonged, there is a certain degree of numbness of the skin; while the pulse becomes small, and may fall from ten to twenty beats in the minute. After a short time (the colder the water the shorter), reaction takes place, bringing redness to the skin and increase of temperature, with a certain amount of excitement; but if the bath be continued, the depression returns. The immediate action of the cold bath is to cause the capillaries to contract and repel the blood from the surface, while by its operation on the peripheral extremities of the nerves, it acts upon the central nervous system. In its more remote effects, the cold bath accelerates the transmutation of tissues, augmenting the excretion of carbonic acid and of urea from the system, and, as a consequence, increasing the appetite.

The body is usually immovable at once in cold water, but the shock of this may be diminished by first using tepid water, and then gradually adding cold to it.

The effect of a cold bath depends much on its duration. Brief immersion, that is for three or four minutes, makes both the depressing and the exciting action less; a longer duration, say of ten to fifteen minutes, increases both actions, but if the bath be very protracted, the continued abstraction of heat produces depression only. The effects of a cold bath are less intense, if the bather is able to keep himself in motion, and especially if he swims.

2. *The Warm Bath.*—A warm bath of 96° to 104° produces no shock to the system; it causes a moderately increased flow of the circulating fluids to the surface, augmenting the frequency of the pulse; and scarcely affects the respiration. There is not the depression or the excitement of a cold bath. It rather retards the transmutation of tissues. With a hot or very hot bath—from 104° to 114°, the central nervous and circulatory systems are more affected. The frequency of the pulse increases greatly. The respiration becomes anxious and quickened. The skin is in a hyperæmic condition, and a free perspiration breaks out.

3. *The Tepid Bath.*—Tepid baths of the temperature of 85° to 95°, are intermediate between cold and warm. Their effects seem to be confined to the peripheral extremities of the nerves, and they do not excite the nervous centres or the circulatory system. Neither the pulse nor the excretions and secretions are affected. As no heat is confined in the system or taken from it, there is no reaction, and the animal temperature is unaltered.

It need scarcely be said that drying and rubbing after a bath materially assist its action on the skin; or that, according to circumstances, it may be convenient to order a whole bath, a hip-bath, or a slipper-bath. The foot-bath is a very useful and convenient one, especially when some stimulant preparation is added to the simple water.

Wet packing and the various processes of hydro-pathy, and those powerful agents hot and cold affusion, whether as shower-baths or as douches, are described in the article on HYDROPATHY.

The *duration* of a bath must depend on a variety of circumstances, for instance, on the age and constitution of the patient, on the nature of his malady, and on the temperature of the bath. It may vary from a few minutes to many hours. A very hot or a very cold bath can be supported for a much shorter time than a tepid one.

ACTION AND USES.—Cold baths are indicated for the strong, for youth, and for manhood, warm baths for the delicate, for women, for early childhood, and for old age. Tepid baths are suitable for almost all constitutions, sexes, and ages. Cold baths may in a general way be considered tonic and bracing; they are useful when judiciously employed in many nervous affections, as in chorea and hysteria, and they are the best of all for general hygienic purposes. Of late years they have been specially employed in the treatment of fever (see article TEMPERA-TURE). The great value of warm baths, besides their hygienic employment, as better detergents than cold ones, is in soothing and reducing excitement; in relieving spasms, such as colic and retention of urine, in the convulsions of children, combined with the affusion of cold water on the head; in cases of gout and rheumatism; and generally when action on the skin is desired. Where prolonged immersion is wanted, tepid baths are indicated, as in calming many chronic nervous disturbances, and in many cutaneous affections.

As to contraindications, all baths, and especially prolonged and even tepid baths are not suited for the asthenic. Both hot and cold baths are to be avoided where there is a weak, fatty heart, or any tendency to apoplexy. No one should ever enter a cold bath when exhausted, and such baths are also contra-indicated when there is a tendency to congestion of internal organs. Under such circumstances a warm bath is usually both safer and more refreshing. The too long and too frequent use of hot baths is debilitating.

II The Simple Vapour-Bath.—A vapour-bath is one in which the skin is exposed to the action of hot water presented in the form of vapour. The vapour-bath may be taken in a box with the head included or not; or in the more common form of the Turkish or Russian baths, where a large room is filled with vapour, and where therefore the vapour is inhaled; or by vapour obtained from a small and suitably constructed apparatus, which vapour may be diffused over the whole body or directed to a particular part. A very simple apparatus for the vapour-bath may be prepared by placing under a chair a shallow earthenware or metallic pan, containing boiling water to the depth of three or four inches, and from which abundant vapour can be obtained by placing in it one or two red-hot bricks. The patient sitting on the chair, surrounded by blankets and other suitable covering, will receive the full benefit of a vapour-bath. Vapour-baths produce profuse perspiration, and act in cleansing the skin much as hot-water baths do, only more powerfully. Vapour being a

slow conductor, does not act so fast on the body as water. Vapour-baths can be borne hotter than warm-water baths, but their use cannot be continued so long, as vapour interferes with radiation of heat from the body. In such baths a heat of more than 122° is not borne comfortably. The vapour-bath, though falling considerably short in temperature of the air-bath, raises the heat of the blood somewhat more. The great virtue of these baths is in their sweat-producing properties. The average loss of perspiration by the use of a Russian bath has been set down at from $\frac{3}{4}$ lb. to 3 lbs. In the Russian bath a slight degree of stimulation of the skin is caused by switching it with twigs of birch, and the alteration of depression and excitement of the cold bath is obtained by placing the patient, when in a state of profuse perspiration, under a douche of cold water.

III. The Simple Hot-Air Bath.—There are two forms in which the hot-air bath is administered: according as the patient does not or does breathe the heated air. The action of the latter closely resembles that of a vapour-bath, but differs from it in not impeding the respiration, as the latter does by depositing moisture in the bronchial tubes. The lungs, instead of requiring to heat up the inspired air, are subjected to a temperature above their own. Hot-air baths favour the highest degree of perspiration, while the moisture of vapour baths somewhat retards it. If they are very hot, they raise the temperature of the body by several degrees.

As the arrangements for vapour- and hot-air baths are practically the same (except that in the latter it is attempted to exclude all vapour from the *calidarium* or *sudatorium*, the hottest room), the following description of an ordinary hot-air bath, the arrangements of which are closely copied from the Romans, will answer for both.

The patient after unclothing first goes into the *tepidarium*, which has a temperature of 113° to 117°, in which he remains until the perspiration bursts forth, which happens in from twenty-five to forty minutes. He next proceeds to the hottest room or *calidarium* (in which the air is heated by hot-air pipes which are inserted in the walls), of a temperature of 133° to 140°, and remains there until the perspiration runs down his skin in twelve to eighteen minutes. An attendant then rubs off the perspiration with a woollen glove, and kneads all the muscles for four or five minutes. The patient next betakes himself to the *laconicum*, where he has water poured over him of the temperature of 81° to 86°; next, the whole body is soaped over, the suds are rubbed off, and the patient goes to the *frigidarium*, where he lays himself on a couch and waits till his skin is completely dry. This may occupy twenty-five to thirty minutes, when the patient dresses and leaves the bath greatly refreshed.

Such is a brief account of these baths, the revived use of which is at present so general. The arrangements vary in detail. For ordinary purposes it is easy to furnish either vapour- or hot-air baths. A great variety of apparatus have been invented for this purpose, which resolve themselves into this, that the patient should lie in bed or on a seat, and have the bed-

clothes or other covering secured from contact with him by the employment of a framework or cradle. Beneath this hot air or vapour is introduced, either directly or indirectly, from a suitable apparatus.

The Sand-Bath.—We may here mention baths of sand, which are a very old remedy. Of late years establishments for supplying them have sprung up in various towns. They are a convenient way of applying dry heat either locally or generally, and are employed in chronic rheumatism. Bags filled with heated sand are useful in hospital and in domestic practice.

Uses.—Both hot-air and vapour-baths are indicated when increased action of the skin is desired. They are used most for the cure of catarrhs, of neuralgic and rheumatic pains, and sciatica. They have also been much employed for reducing obesity. They are useful for general hygienic purposes, but are apt to be given too indiscriminately. Hot-air and vapour-baths are often locally applied with great advantage to a hand, or leg, or arm, in rheumatism or thickened joints.

B. COMPOSITE, MEDICATED, OR ARTIFICIAL BATHS.—A great variety of substances have been used in baths at different periods. We must confine ourselves to such as are at present in use and appear to be of some real value, omitting even some that are employed, such as baths of iodine, of iodide of potassium, of iron, of fermented grapes, and of wine.

1 Composite Liquid Baths.

1. The Sea-Water Bath.—The average amount of salts in sea-water may be set down at 3 per cent.; this may therefore be considered a suitable strength for ordinary salt baths. The quantity commonly used in London hospitals is about 9 lbs of salt to 30 gallons of water. Some use bay salt, others Tidman's. Owing to the high price of sea-salt in inland continental places, various natural salts, some of them containing a comparatively small amount of chloride of sodium, have been suggested as substitutes, and also, for economy's sake, 22 to 25 gallons have been set down as a minimum amount of water for the bath of an adult. The value of these substitutes can only be determined by observing the degree in which they stimulate the skin. Apparently it does not matter much what particular salt is employed to produce the stimulation. A salt-bath can of course be increased to any strength by the addition of salt, or of the mother lye as it is termed.

The chief uses of salt-water baths are as tonic remedies, especially for the young, when there is any tendency to scrofula or chlorosis; also in convalescence from many diseases.

2. Alkaline Baths.—Alkaline baths may be made by adding 6 ounces of crystallised carbonate of soda, or 3 ounces of carbonate of potash, to 25 or 30 gallons of water. Alkaline baths are of use in a great variety of cutaneous affections.

3. The Corrosive Sublimate Bath.—Baths of corrosive sublimate are occasionally employed. They are commonly made by adding 3 drachms of corrosive sublimate and 1 drachm of hydrochloric acid to 30 gallons of water. They are employed in some skin-affections, and in secondary syphilis.

4. Sulphuret of Potassium Bath.—Baths of sulphuret of potassium are made by dissolving from 4 to 8 ounces of that salt in 25 to 30 gallons of water. A little dilute sulphuric acid is sometimes added. These baths have long been extensively employed in the treatment of cases of skin-disease in which the sulphur that they contain is indicated.

5. The Nitro-Muriatic Acid Bath.—The nitric or rather the nitro-muriatic acid bath is made by adding nitro-muriatic acid to water. The ordinary proportion is one ounce of acid to one gallon of water. The discolouring action on clothing makes a full bath of this kind inconvenient for domestic use, and it is best to take it in a bathing establishment. For the ordinary purposes of a foot-bath at home the old directions of Dr. Helemin Scott, who introduced the use of the acid, are sufficient. The vessel must of course be of wood or earthenware. Dr. Scott added four to six ounces of the acid to three gallons of water. This made a rather strong foot-bath. The patient was to keep his feet immersed for thirty minutes: and the bath was to be repeated every other day for two or three weeks. The axilla, the groin, and the region of the liver were to be sponged with the acid solution. The bath causes slight tingling of the skin and a taste in the mouth, and is believed occasionally to produce salivation. This bath has been used very extensively in India and in England in liver affections. There is difference of opinion as to its value, many have great confidence in it.

6 The Bran Bath.—The bran bath is made by boiling four pounds of bran in one gallon of water, straining, and adding the liquor to a quantity of water sufficient for a bath. Such a bath is useful in allaying the irritability of the skin, and also in diminishing the stimulating effect of other baths.

7. The Fucus Bath.—This is made by adding a decoction of sea-weed, or the sea-weed chopped up, to an ordinary bath; it will become more or less gelatinous if enough be added. Such baths go popularly by the name of *Ozone baths*, and they contain a certain amount of chloride of sodium and a minute proportion of iodine. They are useful in the same cases as sea-baths.

8 The Mustard Bath.—An extremely useful stimulating bath is the well-known mustard bath, which is made by adding a handful or two of mustard to the ordinary hot bath. The pediluvium is its most useful form.

9. Pine Baths.—Baths of the balsam of pine-leaves may be prepared extempore by making decoctions of the fresh leaflets at certain seasons; but the usual way is to add about one pound of the extract which is prepared from the leaves, and is everywhere for sale—at least in Germany. The extract dissolves in the bath, which is then ready for use; but of late it has been usual to add a small amount of an essence which is also prepared from the leaflets. It floats to the surface of the water, and attaches itself to the person on leaving the bath, and its aroma is grateful. Of course the quantity of the extract to be employed depends on its strength. These baths are at present largely employed. They are slightly stimulant, and are much used in hysterical, rheumatic, and gouty

affections, and also as an adjunct to the internal use of mineral waters.

10. *Baths of Conium, Lavender, &c.*—Aromatic or sedative baths are prepared by adding a decoction of lavender, hyssop, or conium to an ordinary bath.

It is scarcely necessary to add that, as a rule, all composite liquid baths should be of a temperature a little above the tepid; and that their strength, and the time that the patient is to remain in them, must be determined by the special circumstances of the case.

11. *Composite Vapour-Baths.*—Vapour-baths impregnated with *fr balsam* are popular, and are considered to be more powerful in their operation than pine-baths. The vapour which rises in making the decoction of pine leaves is conveyed to a box in which the patient is enclosed.

Aromatic vapour-baths may be given by making the steam of hot water pass through bunches of fresh aromatics (*conium, lavender, &c.*) before reaching the box in which the patient is placed. Such baths may be useful in hysteria.

111. Composite Air-Baths.

1. *Sulphurous Acid Bath.*—A valuable mode of applying sulphur in the form of a bath is by using its fumes—in other words, sulphurous acid. The patient is seated on a cane-bottomed chair, and his body is encircled with a cradle, over which oil-cloth is thrown, the head remaining uncovered. Sulphur is placed on a metallic plate, to the lower surface of which the flame of a lamp is applied, when sulphurous acid is disengaged. This bath is less used in cutaneous affections than formerly.

2. *The Mercurial Vapour-Bath.*—Very similar is the mode of applying the fumes of mercury. Under the chair are placed a copper bath containing water, and a metallic plate on which are put from 60 to 180 grains of the bisulphuret or of the grey or red oxide of mercury. Spirit lamps are lighted under the bath and under the plate. The patient thus experiences the effects both of aqueous and of mercurial vapour. At the end of five or ten minutes perspiration commences, which becomes excessive in ten minutes or a quarter of an hour. The lamps are then to be extinguished, and when the patient becomes moderately cool, he is to be rubbed dry. He should then drink some warm liquid and remain quiet for a time. This has often been a favourite mode of treating secondary syphilis with some practitioners. Calomel, in quantities of from 20 to 30 grains, is administered in a similar manner, under the name of the *Calomel Bath*. It may be given locally by a suitable apparatus.

BELL-SOUND. A peculiar physical sign associated with pneumothorax. See PHYSICAL EXAMINATION.

BELL'S PARALYSIS. (Named after Sir Charles Bell.) A synonym for paralysis of the facial nerve. See FACIAL PARALYSIS.

BERIBERI.—SYNON.: Barbiere, and numerous other local names.

DEFINITION.—A disease characterised by anæmia, anasarca, degeneration of muscular tissue, effusion into the serous cavities, debility, numbness, pain, and paralysis of the extremities, especially the lower; precordial anxiety, pain, and dyspnoea; scanty and high-coloured urine, and in some cases drowsiness or sleepiness. Beriberi occurs in a chronic and an acute form, in the latter often proving rapidly fatal from exhaustion, syncope, or the formation of cardiac or pulmonary coagula.

ETYMOLOGY.—The etymology of the word Beriberi is obscure. Herklotts suggests the Hindi word, *Bhêrêr*—a sheep—from the fancied resemblance of the gait of persons affected to that of sheep. *Sood-bhêrêr* comes from the words numbness and sheep. *Sood-ko-burêe* signifies numbness and rheumatism. *Bhêr-bhêr*, a Hind. word, signifies a sore, a swelling. Minson Good says that Bontius introduced the word Beriberia, and tells us that it is of Oriental origin. Carter suggests *Bhar*, sailor, from *Bahr*, the sea; and *Bhagr*, shortness of breath. As the disease is seen among African and Arab sailors, this is probable. Some think it is derived from a Cingalese word meaning weakness, first applied to a variety of conditions, the result of scorbutic, malarious, rheumatic, and anæmic cachexiæ, on the Malabar Coast.

GEOGRAPHICAL DISTRIBUTION.—Beriberi prevails endemically in Ceylon; and in India, on the Malabar Coast, and in the Northern Circars, between 13° and 20° N latitude, extending inland from forty to sixty miles. It is known in other parts of India, probably occasionally all over the peninsula; in Barmah and the Malayan peninsula; amongst the crews of ships trading to ports in the Persian Gulf, Red Sea, coast of Africa, Bay of Bengal, Singapore, Siam, and the islands of the Indian Archipelago, and in the Australian seas. On the West Coast and other parts of Africa beriberi also occurs, and is known as the *sleeping sickness*. In Europe *pernicious anæmia* is possibly the same disease. Beriberi is also met with in South America, and probably wherever certain conditions of food, water, soil, climate, and mode of life coexist.

ÆTIOLOGY.—All observation tends to show that beriberi occurs where causes of debility have for some time operated, especially in the climates and localities previously mentioned, such as certain conditions of soil, air, and water; exposure to great alternations of temperature, especially when accompanied by wet, fatigue, mental and physical depression; food deficient in quantity and quality or variety; previous exhausting diseases; malaria, and other undefined atmospheric and telluric influences—all, in fact, that tends to depress the vital energies, impoverish the blood, and starve the nerve-centres. The symptoms, it is said, seldom begin to appear within ten months or a year after first exposure to these causes. Beriberi has been ascribed by Ranking to disease of the kidney, but there is no evidence to prove that it is due to this cause, or indeed to structural changes of any of the viscera. Morehead refers it rather to a scorbutic rigidity and in some respects it does resemble

scorvy; it may probably, also, be a consequence of the cachexia that so often results from long residence in a malarious climate, especially when that has been accompanied by exposure, privation, and excessive exhaustion of the vital powers. In such, the most complete anemia, with debility, may occur, independently of the existence of organic visceral disease, though naturally they will be intensified where such disease is present.

ANATOMICAL CHARACTER.—Serous fluid is effused generally—in the areolar tissue, in the lungs, brain, heart, and abdominal viscera. The cavities are, like the tissues, soaked with watery effusion. The tissues are soft and degenerate. Muscular fibre is fatty, especially that of the heart, which is often enlarged and dilated. The kidneys are enlarged, anemic, and softened.

PATHOLOGY.—The recent discovery by Mr. T. Lewis in India, of the embryo of a nematode worm in the blood of persons suffering from chyluria (see CHYLURIA), lymphorrhœa, and elephantiasis, of which diseases it appears to be to some extent the cause, suggests inquiry whether a similar hæmatozoon may not also be in some way concerned in inducing beriberi. Fousgrives and Leroy de Mericourt describe beriberi as general dropsy with a rapid course, no albuminuria, and weakness and loss of sensibility in the lower limbs. Dropsy commences as anasarca, and extends to the serous cavities. Though hepatic, splenic, or renal complications may exist, and intensify the severity and hasten the progress of the general symptoms, they are not essential concomitants of the disease, but appear to originate in a spæmic state of the blood, and to be kept up by its progressive imperfect elaboration. The resulting partial starvation of the cerebro-spinal nerve-centres, and the serous effusion into and amongst them, sufficiently account for the paralysis which, in severe cases, characterises this disease.

SYMPTOMS.—Beriberi presents itself under a *chronic* and an *acute* aspect, rarely, it is said, ever occurring in either form, until after an exposure of some months to the exciting causes. The general symptoms may be said to be those of anemia and anasarca. Edema pervades the limbs and body generally, accompanied with numbness, pain, heaviness, and loss of power, amounting in some cases to paralysis. Along with these symptoms there occur præcordial anxiety, dyspnea, irregularity and palpitation of the heart, pain at the ensiform cartilage, anemic murmurs, debility, and a small quick pulse, which at the outset may be rather hard and full, accompanied by dryness and heat of skin. The appetite is at first not impaired. Later there is coldness of the extremities; torpor of the bowels; scanty, high-coloured urine, of sp. gr. 1020 to 1040, but no albuminuria as a rule. According to Horton and others, excessive drowsiness and stupor attend some stages of certain cases of the disease; also pale, flabby tongue and blanched mucous membranes; occasionally hæmorrhage from the stomach and bowels; with petechial eruptions; an anxious look; a puffy, swollen, and sometimes livid face; and a peculiar tottering gait. Death results rapidly in some of the acute cases, with symptoms of effusion

into the thoracic and abdominal cavities, or within the skull, by exhaustion, syncope, or the formation of coagula, either in the systemic or in the pulmonary circulation. Beriberi frequently assumes a slight and modified form, indicated by anemia, numbness, and a certain amount of pain in the limbs; an anxious expression; disordered bowels, scanty urine; cold skin; a low, feeble, and irregular pulse; præcordial pain or uneasiness, with palpitation; nervous depression; an unsteady, almost tottering gait; and a puffy face and neck. Dr. Paul says: 'I have met with a numerous class of cases that are not so serious (as the acute) or so often fatal, where the chief symptom complained of was burning of the feet.' Malcolmson describes this remarkable condition in connection with beriberi, to which, he says, it is allied—it is found to affect the soles and calves of the legs, the back, and occasionally the muscles of the legs.' It occurs in recent and slight examples of beriberi, and was first observed in the troops after the first Burmese war—sometimes in men who had not had beriberi; on the whole, Malcolmson thinks it is neither rheumatism nor beriberi, and may accompany or follow other diseases, as an indication of nervous debility.

In the *acute* forms of beriberi the symptoms are very severe and often rapid; and the mortality would indicate it to be second only to cholera in fatality. The chief symptoms are:—Rapid general anemia and dropsy of the cavities; scanty, almost suppressed urine; constipation; weak, irregular pulse; intense præcordial pain; hurried, irregular, and painful breathing; occasional vomiting—sometimes of blood; swelling of the limbs, with numbness, pain, and paralysis, preceded by a feeble, tottering gait; all the symptoms of pleuritic and pericardial effusion; failing heart, and death either from syncope, or perhaps almost suddenly from embolism—in the most acute cases within a few days. In this acute form the affection is very fatal, but in the milder and more chronic form recovery is frequent. Acute cases often supervene in those who have suffered from the milder disease, or in those who are exhausted and anemic from other causes.

TREATMENT.—Attention to diet, suitable clothing, and protection against vicissitudes of temperature, wet, and cold, are the best *preventive* measures. Bad hygiene and exhausting habits of life tend to promote the development of the constitutional condition in which the disease commences.

When beriberi is established these precautions are still necessary, and attention must be paid to the symptoms as they occur. Diuretics and diaphoretics relieve the edema and dropical effusions. Tonics and stimulants give vigour to the weakened muscular fibre; while appropriate remedies and diet may improve the condition of the blood.

Acetate of potash, digitalis, and squill, and occasionally calomel, are said to favour the removal of the fluid. It is needless to say that the physiological action of mercury is to be avoided. Salines, hot-air baths, diaphoretics, and turpentine may at various stages be found useful. The object being to remove the fluid and

strengthen muscular fibre, quinine, *ir. u.*, and other tonics are an important element in the treatment. No remedies, however, will be of much avail unless the patient be placed in favourable hygienic conditions. Malcolmson speaks highly of two remedies—*trick farook*, and *oleum nigrum*, which are considered to be very effective in the treatment of the disease, especially in relieving the dyspnoea and oedema, which proved very fatal until these drugs were introduced. The composition of the *trick* is apparently generally unknown—it seems to be diuretic and stimulating, and probably not aperient unless combined with rhubarb, in doses of four to fifteen grains. The *oleum nigrum* is a stimulant and diaphoretic, given thrice daily, and has been found by Indian physicians to be very beneficial in some cases of beriberi. Dr. Aitken says that turpentine is a useful remedy. Ergotin, iron, and belladonna with zinc in the form of pill, accompanied with sea-bathing, were useful in this disease, as seen at Bahra. Nuxvomica has often been found serviceable in certain cases, as might be expected, and opium may be needed to allay pain and irritability. Hepatic and splenic complications need their appropriate remedies. Obviously the chief indications are to promote removal of the oedema; to regulate the functions of the abdominal viscera, to increase the action of the skin; and to give tone and vigour to the muscular fibre. By such measures can we alone hope to deal successfully with this profound form of cachexia. JOSEPH FAYRE.

BIARRITZ in France, on the Bay of Biscay. A fashionable sea-side resort. The climate is considered to be bracing. See CLIMATE, Treatment of Disease by.

BILE, Disorders of.—Disorders of the bile held a large place in the medicine of antiquity, with the exception of the theories of Van Helmont and Paracelsus; the latter looking upon the bile as the balsam of life, and therefore incapable of begetting disease; the former regarding it as a mere excrementitious fluid, and therefore equally incapable of begetting disease. Disorders of the bile have, nevertheless, held their own quite into our time. It is common enough to hear persons speak of a 'bilious attack,' or 'being troubled with the bile,' expressions the survivals of the humoral pathology. The liver was formerly credited with most of the dyspeptic disorders of the stomach. As Sir Thomas Watson says, it is an organ often blamed most gratuitously and unjustly, but no educated or scientific physician would now think of attributing a gastric catarrh, or constipation, to an 'attack of the bile,' or to a 'sluggish liver.'

Physicians have arranged disorders affecting the bile under three heads—(1) diminished secretion of bile; (2) increased secretion of bile; and (3) secretion of morbid or altered bile. This division may very well be accepted as a convenient basis for the further discussion of biliary disorders, but it is nothing more than an hypothesis. It is likely enough that the bile, in certain diseases, changes its character as regards both its amount and constituent parts: but it cannot be denied that the means by which physicians are able to ascertain these changes can scarcely be

said to exist in ordinary cases. A common saying is that the patient must be making plenty of bile because the stools are high in colour. No reasoning can be more fallacious. The colour of the stools may be high if the feces be quickly swept through the intestinal canal, because there has been no time for the bile-pigment to be absorbed into the blood. Or the feces may be pale if they lie long in the bowel and the coloured matter absorbed. So that the colour of the stools is no sure sign of the poverty or abundance of the secretion of bile. In cases of pale, coloured faces purgatives often do good, not because they have any special tendency to increase the flow of bile, but because they hurry the feces out of the intestine, and thus give no time for the absorption of the bile, which, if it lay long in the bowel, would be absorbed, carried to the liver, and again excreted into the gall-ducts—the vicious circle of Schiff.

Nor is the analysis of the bile found after death in the gall-bladder of much value. Frerichs announced the presence of albumen in the bile in cases of congestion of the liver; but it is now generally thought that this appearance is due solely to a *post-mortem* transudation. Ritter also has described a colourless bile in which all the constituents of bile are present except the pigments. Most of his analyses were made on bile taken from the gall-bladder after death; but if the cystic duct be obstructed for any time, it is well known that the bile contained in the gall-bladder may become colourless without any real secretion of colourless bile having taken place in the first instance. It is impossible to be certain that the changes, which are found in the bile taken from the gall-bladder after death, have taken place during life.

The only source of what may be called knowledge of the disorders of the bile is observation of men or animals in whom biliary fistulae have been formed either by disease or by art. Unfortunately, the majority of such observations have been physiological or pharmacological; and but few are recorded of the changes which the bile undergoes in disease. Altogether contradictory experiments are recorded of the influence of the nerves and of the diabetic puncture of the fourth ventricle upon the secretion of bile. It is an admirable field for further research, but it will be seen that our present knowledge very closely approaches to complete ignorance.

It is disputed still whether the presence of bile in the stomach puts an end to the process of digestion. By many it is thought that the bile-acids throw down the albumen of the food, and with the albumen the pepsin. It is well known that in some disorders there is an inverted action of the duodenum, and bile is poured into the stomach, as in long-continued vomiting, for instance; thus the dispute has a practical bearing. The best treatment of this state would seem to be by saline purgatives.

Bile may also be taken up into the blood, and when this occurs, jaundice results (*see JAUNDICE*).

J. WICKHAM LOGG.

BILHARZIA.—This name was given by the writer to a genus of flukes discovered by Dr. Bilharz, of Cairo, in the portal system of human

blood-vessels, and the worm was subsequently found by the writer in the portal vein of a monkey. This trematode hematozoön was first described as a *Diatoma*, but the species is now more generally known as the *Bilharzia hematobia*. It was originally found in the portal system, and Bilharz, Griesinger, Leutner, and others afterwards showed that this parasite also infects the veins of the mesentery, bladder, and other parts, producing a formidable disease which is endemic in Egypt, at the Cape, at Natal, and probably in other parts of the African continent, as well as in the Mauritius. The discovery that the endemic hæmaturia of the Cape of Good Hope is occasioned by the presence of *Bilharzia*, is due to Dr. John Harley, who detected the ova in the urine of a patient who had previously resided in Southern Africa. Dr. Harley's impression that he had to deal with a new species of *Bilharzia* has not gained general acceptance, but he furnished proof of the wide geographical distribution of this parasite, and he also added largely to our knowledge of its ravages.

DESCRIPTION.—This parasite, unlike nearly all the other known species of fluke, has the sexes separate, the females being comparatively slender worms, resembling filariform nematoids. During copulation the female is lodged in a long slit-like groove, or gynæceophoric canal, with which the abdomen of the male is furnished.

FIG. 2.—*Bilharzia hematobia*, male and female sexually combined. Magnified. After Küchenmeister.

FIG. 3.—Ovum of *Bilharzia hematobia* with contained embryo and free sarcode-granules. $\times 234$ diameters. Original.

The eggs, measuring from $\frac{1}{100}$ " to $\frac{1}{100}$ " in length, are peculiar, being either sharply pointed at one end, or furnished with a projecting spine, placed at a little distance from the hinder pole. This spine gives a point of resistance to the egg during the struggles of the embryo to effect its escape. Those who are interested in the organization of the ciliated embryos, and in the remarkable behaviour of the larvæ during their earliest stages of growth, will find the subject fully discussed in the writer's paper 'On the development of *B. hematobia*,' together with remarks on the ova of another urinary parasite, occurring in a case of hæmaturia from Natal, *Brit. Med. Journ.*, 1872.

TREATMENT.—The writer has pointed to the danger of treating cases of *Bilharzia* as if they were comparable to ordinary helminthiases. It is neither desirable to employ active drugs for the

expulsion of the parasite and its eggs from the bladder, nor is it prudent to attempt the employment of vermicides with the view of destroying the worms. As in Trichinosis, so in the *Bilharzia* disease, it is essential to support the system. Thus tonics, cold bathing, and a highly nourishing diet, combined with the bicarbonate of potash and infusion of buchu, constitute our best resources when dealing with cases of endemic hæmaturia. The pathological facts clearly show that in order to effect a cure we must imitate nature herself as closely as we can. We must seek to erect artificial barriers, and thus check the hæmorrhage as much as possible. For this purpose the writer has found the astringent properties of *Arctostaphylos uva ursi* eminently serviceable; small quantities of hyoscyamus being usefully combined. Dr. Harley advises 'a perovrating use of belladonna and henbane,' under the impression that treatment with these drugs 'will retard the development of the parasite, even if they do not effect its destruction.' The writer entirely disagrees in this view of the case, and he also objects to the employment of medicated injections. He thinks that the employment of diuretics is likewise clearly contra-indicated. Everything that will contribute towards allaying the vesical irritation, is certain to assist the natural process of cure; and, in this view, the administration of buchu-infusion, the enforcing of a liberal diet, and the taking of gentle exercise, will be found amongst the most important curative aids. In bad cases a thorough cure is not likely to be completed until after the lapse of several years. Prophylactically it is essential to remove patients from the localities in which there is every reason to believe they have contracted the disease. In view, also, of preventing infection on the part of others, it is necessary that the water employed for domestic purposes throughout the infected districts, be rendered thoroughly pure by efficient filtration. For further particulars the reader is recommended to consult the general works of Küchenmeister and Leuckart, the writer's introductory treatise on *Entozoa* (p. 197 et seq.); Dr. Harley's three separate memoirs (in the *Transactions of the Royal Med. and Chir. Soc.*, 1864, &c.); and also especially the recent memoir by Dr. Sansino, entitled 'Researches concerning *Bilharzia hematobia* in relation to the endemic hæmaturia of Egypt, with a note on a nematoid found in human blood' (*Rend. della R. Accad. delle Scienze*, &c., 1874). See also HÆMATOZOA.

T. S. CORBOLD.

BILIARY CALCULUS. See GALL-STONES.

BILIARY FISTULA.—There are two kinds of biliary fistula:—one, in which a communication exists between the gall-bladder and the surface of the body; the other, in which there is a communication between the gall-bladder and other internal organs. Neither kind is common, but the first is less rare than the other.

In the first variety a tumour forms, sometimes in the place of the gall-bladder, at other times near the umbilicus, in the linea alba or to the left of this line, or in the groin. The tumour, if opened spontaneously or by the surgeon, discharges a quantity of pus, bile, and gall-stones. If the cystic duct

be obliterated, no bile need escape. A suppuration of the gall-bladder, caused by the presence of gall-stones, is the common cause of these fistulae. The prognosis is good. The diagnosis, before the tumour opens, is very difficult. In a case which came under the writer's notice, it was mistaken for an abscess of the liver.

In the second kind of biliary fistula, the gall-bladder may communicate with the duodenum or colon; with an abscess of the liver; with the portal or other abdominal vein, though it must be owned that cases of this kind seem somewhat dubious; or with the urinary bladder, or at least with some part of the urinary tract. Gall-stones are in nearly every case the cause of the fistulous opening. J. WICKHAM LEGG.

BILIOUS.—This term is used with much vagueness, and in popular language is often employed very incorrectly, though the idea is to associate it with conditions in which an excessive formation of bile is supposed to occur. The chief uses of the word are as follows:—In the first place it is employed to designate a peculiar temperament—the *bilious temperament*. Again, individuals are often said to be *bilious* when they present a sallow or more or less yellowish tint of skin, but especially if they are distinctly jaundiced. *Bilious vomiting* and *diarrhoea* signify respectively the discharge of a quantity of bile, mixed with vomited matters or with loose stools. Certain febrile diseases, attended with yellowness of the skin, are sometimes designated *bilious fever*, and under like circumstances pneumonia has been described as *bilious pneumonia*. Lastly, one of the most frequent applications of the term is to certain so-called *bilious attacks* or *biliousness*, which, however, are commonly merely attacks of acute dyspepsia or migraine. The most prominent symptoms of a supposed *bilious attack* are anorexia, furred tongue, a bitter taste, sickness, constipation, and headache, with a feeling of marked depression and general malaise. Such attacks are most effectually prevented by careful regulation of diet, and the avoidance of exposure to cold, fatigue, and undue mental exertion or anxiety; when they come on, abstinence from food is desirable, with rest in the recumbent posture, and perfect quiet. Alterative aperients and saline effluents may be given, alcoholic stimulants being avoided as far as possible. FREDERICK T. ROBERTS.

BILIOUS TEMPERAMENT. See TEMPERAMENT.

BITTER ALMONDS, Poisoning by. See PRUSSIC ACID, Poisoning by.

BLACK VOMIT.—Vomited matters may be more or less black in different diseases, but the peculiar *black vomit* is that which occurs in yellow fever (see YELLOW FEVER).—The rejected matters are acid in reaction, and a sediment is deposited of coagulated albumen and disintegrated blood-corpuscles. Ammonia is also present. The black colour of the vomit has been attributed by some writers to altered bile, but there can be no doubt that it is due to its admixture with blood which has undergone certain changes.

BLADDER, Diseases of.—The bladder may

be the seat of the following morbid conditions:—Inflammation, acute or chronic; Abscess; Neuralgia; Atrophy or Hypertrophy; Mechanical Distension, with chronic engorgement and retention of urine, commonly, but erroneously, termed 'Paralysis'; Sacculations; Displacements, such as hernia in the male, or, very rarely, inversion and protrusion in the female; Tumours or Growths, including fibrous, villous, or vascular growths; Epithelioma and Carcinoma; Tubercular Disease; Ulceration, either simple or malignant; and Vesico-vaginal or Vesico-intestinal fistula. The bladder may also be the subject of true paralysis, partial or complete, as the result of injury to the brain or spinal cord, or following disease of those organs.

Only a brief statement respecting the most important of this class of affections need be presented here, in order to facilitate an acquaintance with their diagnosis, since the treatment of almost all of them belongs to the province of the surgeon, and so far only as it consists of medicinal remedies will the subject be considered.

1. Acute Inflammation—Acute Cystitis.—The mucous lining of the bladder is the part affected by inflammation—and although after long and severe attacks some morbid action occurs by extension to the muscular coat, or even to the peritoneal covering, these structures are very rarely affected. An acute inflammation of a very severe kind occurs from injuries; from the presence of instruments, foreign bodies, or calculi; and from unrelieved retention of urine. A less severe, somewhat evanescent, but very painful form of cystitis arises from irritants taken internally, as cantharides. A still less severe, but often troublesome form originates by extension from gonorrhoea.

In the *first class of cases* there are not only severe local symptoms referable to the bladder, but the general system may be gravely affected.

In the *second class*, of which cantharides-poisoning is the type, the phenomena of very frequent, painful, and spasmodic attempts to eject small quantities of urine which is often bloody, occur within a very short time after absorption of the poison. A common blister is said to produce the affection in some persons. In two cases—the only two the writer has seen—it has followed the application of a blister to a surface already partially denuded of the scurfy skin. In one of these a blister was applied to a knee which had been frequently painted with tincture of iodine, and was still slightly sore. In three hours after the application the patient was attacked with exceedingly painful efforts to micturate, which were at times intense. The attack lasted six hours, gradually diminishing in force, and leaving no ill-effects behind. In less than twenty-four hours no trace of the symptoms remained.

In the *third form* of cystitis, which is the most common, and of which that arising by extension from gonorrhoea may be taken as the type, the usual symptoms are undue frequency of micturition; a necessity to perform the act immediately the want has declared itself, a condition conveniently expressed by the single word 'urgency'; a desire to pass more, accompanied by pain, when all the urine has been voided; and

some dull aching over the pubes; together with a general febrile state of the system, often very slight, but corresponding for the most part with the degree of local inflammation. The urine itself is cloudy, and deposits some light mucus on standing, but is not otherwise apparently altered. Under the microscope abundance of epithelium is visible, as well as some pus-cells, and if the affection is severe, a few blood-corpuscles are also present. It may be remarked here that the presence of a few pus-cells in the urine, a fact to which so many practitioners attribute considerable importance, by no means necessarily deserves to be so regarded. The very slightest attack either of this or of the preceding form of cystitis is certain to be attended by the formation of some quantity, however small, of fully-developed pus-cells.

Very rarely a *false membrane* may be produced on the surface of the mucous membrane of the bladder, and may be thrown off almost entire, leading to the belief that the inner coat has itself been exfoliated. In women this membrane has been voided per urethram in a condition for examination; in men this cannot occur, because the urethra is too small to admit of it. Now and then examples of the former have been shown at the Pathological Society of London, and one of the latter may be seen, discovered by operation, in the museum of the Royal College of Surgeons of London.

TREATMENT.—In the first form of cystitis, the removal of the exciting cause, if possible, is the chief indication.

The treatment of the second form should consist of very hot bidets or hip-baths, the former being probably preferable as capable of being used at higher temperatures than the latter; together with large doses of the tincture of henbane, say a drachm, with 10 or 15 drops of liquor opii every two hours while pain is severe; 20 minims of liquor potassæ may be given either simultaneously or alternately, in water or in any bland diluent.

The treatment of a well-marked case of the third class consists in absolute rest in the recumbent posture, mild diet, abstinence from all alcoholic stimuli, gentle laxative action of the bowels, and the administration of small doses of alkali. The writer prefers liquor potassæ to all others, frequently repeated; and this may be combined with henbane, or, if micturition is very frequent and painful, with opium or morphia, or with chlorodyne in small doses. Hot hip-baths or bidets, followed by hot linseed-meal poultices or fomentations, give great relief. The patient may drink freely of decoction of tritium repens, linseed tea, barley water, or similar demulcents. Relief rapidly follows, but care is requisite to avoid relapse, which easily occurs if exercise be taken too soon, if injections for the gonorrhœa be resumed too readily, or if alcoholic stimulants are freely taken.

2. Chronic Inflammation—Chronic Cystitis.—Chronic inflammation of the bladder is separated from the acute form by very distinct characters. It is mostly the result of retained urine from stricture or enlarged prostate; but it may arise from the presence of calculi, or of growths in the bladder; from over-distension, or atony of

its coats; from paralysis after injury or disease affecting a nervous centre; from disease of neighbouring organs; and sometimes from altered urine: it is also met with in certain affections of the kidney. Sometimes this condition is marked by the presence of a large quantity of viscous mucus, often called 'catarrh'; but more commonly this symptom is absent, and the urine contains merely ordinary mucus or muco-pus, rendering the secretion more or less cloudy and opaque. Perhaps there are some cases in which the inflammation is mainly due to the presence of gout.

SYMPTOMS.—The symptoms of chronic cystitis are increased frequency of micturition and pain, but the latter is by no means necessarily present. The urine is always cloudy, and contains some pus-cells. There is often, but not always, some suprapubic uneasiness. The general health does not suffer unless the affection is prolonged or severe. If important causes, as the presence of stricture, calculus, &c., occasion the chronic cystitis, their specific symptoms will predominate. It is not common to find chronic cystitis as an idiopathic disease, although undoubtedly it occasionally is so; so that the writer has always regarded it as a useful maxim, 'When chronic cystitis is declared to be idiopathic, we may be sure that we have only not yet discovered the real cause.' As a general rule we may be sure that there is inability to empty the bladder, or calculus, stricture, or organic disease of some kind in some part of the urinary tract, when the group of symptoms are present which we denote by the term 'chronic cystitis.' Respecting the well-known glairy mucus, which is deposited so abundantly from the urine in some cases, in elderly people almost invariably, it should be said that it appears only in those whose urine is abnormally retained, through atony of the vesical wall, or in consequence of enlarged prostate, or as the result of accumulation of the bladder, and that medicine has little or no effect upon it.

TREATMENT.—The regular and habitual use of the catheter, and perhaps also injections into the bladder, form the essential mechanical treatment of chronic cystitis in the cases just mentioned. In the few cases in which chronic cystitis is present, and no organic cause, such as those named above, can be discovered—and also as adjuncts to mechanical treatment when these causes do exist—certain medicinal agents are undoubtedly useful: these are buchu, tritium repens, uva ursi, alchemilla arvensis, pereira brava, and the alkalis potash and soda. Buchu is more useful in subacute and recent chronic cystitis than in cases already of long duration. The patient should take not less than ten ounces of the infusion daily. After this, in similar cases, the decoction of tritium repens, made by boiling two to four ounces of the prepared underground stem in a pint or a pint and a half of water, of which six ounces should be taken three or four times in the twenty-four hours, is highly useful. For more chronic cases, where the urine is alkaline and deposits much mucus, and perhaps the triple phosphates also, alchemilla, uva ursi, and pereira brava may be very valuable. The alchemilla is administered in infusion, one ounce of the

herb in one pint of boiling water, of which the dose is four to six ounces three times daily; the others according to the directions of the pharmacopœia. These may be taken alone or combined with potash, which in moderate quantities diminishes the natural acidity of the urine before it enters the bladder; the mucous membrane of which, although accustomed to that condition in health, is perhaps sometimes, when inflamed, irritated by urine of even the ordinary acidity. Whether this be so or not, there is no doubt that alkalis do frequently tranquillise an irritable bladder. They are often given in the form of Vichy water, Vals water, or that of Erian, all strong solutions of soda; but on many grounds the salts of potash are preferable. On the other hand, the mineral acids have been largely administered in cases where the urine is alkaline; although there is no reason to believe that the acid has any direct action through the kidneys, or that it is eliminated by those organs. Alkalinity of the urine in chronic cystitis is almost always due to inability of the bladder to empty itself, and the remedy wanted is not medicine but a catheter, at all events to ascertain whether this be the cause or not. A very small quantity of urine retained in the bladder, say one or two ounces, after every act of micturition, suffices in some cases to maintain an alkaline and otherwise unhealthy state of the secretion: while it is equally true that some patients may habitually, and during long periods of time do fail to empty the bladder, always leaving behind from half a pint to a pint, without losing the acidity of the urine. Of course other signs, and notably great frequency of micturition, are present when such is the case.

3. *Neuralgia*.—It is impossible to deny that the bladder may be, like other parts of the body, subject to symptoms which are described as neuralgia, although the occurrence is an extremely rare one. All the writer can say is, that he has occasionally met with cases in which he has not been able to account, by the existence of any lesion, for pain and frequency in micturition, or for difficulty in performing that act, and where these symptoms have been more or less periodic in their appearance. In such instances he has given quinine, and has occasionally found great relief to follow a few doses; more frequently this has not been the case. But now and then the value of the drug has been so marked as to corroborate a belief in the existence of vesical neuralgia. It must be repeated, however, that examples of such phenomena are extremely rare. The writer has also employed arsenic on the same ground. It is invariably necessary to investigate the general health, as well as the habits and diet of the patient. This, perhaps, may be the place for stating that in all chronic and slight deviations from natural and healthy function in the urinary organs, it is essentially necessary to inquire into the state of the digestive organs, to correct by diet and by medicine when necessary any imperfect action on their part, if possible. Constipation alone, when habitual, may produce considerable irritability of the bladder, so also may the unnecessary use of purgatives. A gentle, easy, and daily action of

the bowels, a healthy condition of the primary digestion, the absence of flatulence and distension after food, should be ensured as far as possible in all patients complaining of frequent, difficult, or uneasy micturition; and many such may be completely cured of so-called urinary affections by strict attention to these matters. The writer's strong convictions relative to this fact, grounded on innumerable experiences of its value as an aid in practice, led him nearly twenty years ago to ascertain the great value, for such patients, of Friedrichshall water, now so extensively used; and more than ever he insists on the use of a mild and laxative regimen and diet in their management.

4. Where obstruction to the outflow of urine exists (stricture of the urethra, most forms of enlarged prostate, other tumours, &c.), the muscular walls of the bladder become the seat of *Hypertrophy*, which is a condition of compensation, therefore, and not of disease in or by itself. But such changes in the interlacing muscular fibres existing, *Sacculation* readily occurs, by protrusion of the lining membrane between the bands so produced. On the other hand, most commonly when the prostate is hypertrophied, the bladder becomes gradually distended, its coats become expanded, thinned and weakened, and a certain degree of *Atrophy* takes place. The power of the organ to expel urine is lost or diminished, and micturition being a function of simply mechanical nature, the circumstances of the case demand only a mechanical remedy, viz. the catheter. No medicine can restore power and exercise of function under these circumstances. But atrophy and loss of power may occur from complete or partial loss of nervous influence to the bladder, as in those who are the subjects of paralytic states commencing in the spinal cord or brain. When the paralytic state follows accident causing injury to a nervous centre, the nature of the case is obvious enough. But sometimes the onset and progress of chronic disease in these organs are very slow and insidious; the urinary troubles, as manifested by slowness or difficulty in passing urine, or by urine clouded through inability of the bladder to empty itself, may be the earliest signs of the nervous lesion. On the other hand, impaired gut, and other evidences of central mischief, may be and mostly are earlier phenomena, the derangement in the urinary function appearing at a later stage. For such patients, the habitual use of the catheter is often necessary [always of course when unable to empty the bladder by the natural efforts]; while such constitutional treatment as is indicated by the cerebral or cerebro-spinal lesion present will comprehend that which the bladder demands. It is therefore unnecessary to allude further to that subject in this article. The same remark also applies to those few examples of *Tubercular disease* of the urinary organs, which is always a local expression of a general constitutional state sufficiently considered under its proper head in this work. All other treatment of this malady is local and surgical.

5. *Relative to Tumours*, the varieties of which have already been enumerated, no medical treatment other than that of chronic cystitis is to be thought of.

With almost all affections of the bladder, simple or malignant, ulcerative or associated with fistula, cystitis to some extent and in some form co-exists. It is this which gives rise to the presence of an undus quantity of mucus in the urine; it is often the source of pus, sometimes of blood in small quantity. Thus in all the above-mentioned diseases, some degree of cystitis appears sooner or later. HENRY THOMPSON.

BLADDER-WORMS.—Entozoa having the character of cysts or vesicles, and being at the same time more or less transparent. This general term embraces a variety of parasitic forms, such as *Echinococci*, *Cœnuri*, and *Cysticercæ*, all of which are the larvæ of different species of tapeworm. Practically, it is important to know the origin of every kind of human bladder-worm, since the adoption of appropriate hygienic measures may prevent infection by each of the various species. See *ECHINOCOCCI*, *CYSTICERCUS*, *HYDATIDS*, *MILK*, *TÆVIA*, and *TAPWORM*. T. S. COBURN.

BLAIN.—A blister, as in the case of chilblain. According to Mason Good, blains are 'orbicular elevations of the cuticle, containing a watery fluid.'

BLEB.—A large vesicle or bulla, containing for the most part a serous fluid, as in pemphigus, erysipelas, or burns and scalds. See *BISTRIK*.

BLENNORRŒA, BLENNORRHAGIA (*Βλεννα*, phlegm, and *ῥέω*, I flow; *Βλέννα*, phlegm, and *ῥήγνυμι*, I burst out). These terms are most correctly used to express excessive flow of mucus from any mucous surface. By means of an affix, the locality or nature of the discharge is expressed: e.g., *blennorrhœa oculi, nasalis, urethralis*. More commonly, however, and less accurately, *blennorrhœa* is employed as synonymous with gonorrhœa in the male or female.

BLEPHARITIS (*Βλεφαρίτις*, an eyelid) Inflammation of the eyelids. See *EYE* and its Appendages, Diseases of.

BLEPHAROSPASM (*Βλεφασμός*, an eyelid, and *σπασμός*, a spasm). Spasmodic movement or contraction of the eyelids. See *EYE* and its Appendages, Diseases of.

BLINDNESS.—Loss of sight. See *AMAUROSIOS* and *VISION*, Disorders of.

BLISTER.—SYNON.: Bieb; Bulla; Fr. *Bulle*; Ger. *Blase*.

DEFINITION.—A vesicle of the skin, caused by the separation of the horny cuticle from the rete mucosum by the transudation of serous lymph beneath the former.

ÆTIOLOGY.—Blisters may be idiopathic, as in pemphigus; or symptomatic, as in erysipelas. They are met with under the influence of any cause which depresses the vitality of the integument, as in some forms of prurigo, in chilblain, and in carbuncle; in scalds and burns; and as an effect of powerful irritants, such as cantharides or the aniline salts.

DESCRIPTION.—A blister ranges in size from that of a pea to a turkey's egg; it is more or less convex according to the amount of exudation; and conforms in colour with that of its contents, being sometimes yellow or amber-coloured and transparent, like serum, sometimes opalescent

from the presence of pus, and sometimes red or purple from admixture with blood. The fluid of a blister, generally limpid and free, is sometimes held in the meshes of a delicate network, resulting from the stretching of the connecting cells of the rete mucosum and horny epidermis. This is peculiarly the case in blisters developed under the influence of acute inflammation, and especially in *Dermatitis anilina*. Blisters may be dispersed, or aggregated, or even single, as in *Pemphigus* or *Pompholyx solitarius*.

TREATMENT.—Blisters are essentially anæsthetic in their nature, and call for corroborant therapeutical treatment. Locally they should be punctured so as to admit of the gradual escape of their contents, and then dusted over with some absorbent powder, such as oxide of zinc, fuller's earth, or cinchona. ERASMUS WILSON.

BLISTERING.—A therapeutic measure which consists in the artificial production of blisters on the skin. See *COUNTER-IRRITATION*.

BLOOD, Abstraction of.—SYNON.: Bleeding, Blood-letting. Fr. *La Saignée*; Ger. *Der Aderlass*. — **DEFINITION.**—The withdrawal of blood from the body, either (a) from the general circulation, by arteriotomy or phlebotomy, or (b) locally, by leeches, scarifications, or wet-cupping.

It is to the first two of these methods of abstracting blood that the term 'bleeding,' or 'blood-letting,' has by common usage been restricted.

The topical abstraction of blood by means of leeches, scarifications, and cupping, though often valuable, is of secondary importance. The present article will, therefore, chiefly be devoted to *general bleeding*.

General Bleeding.—This art, practised for centuries more or less universally, has of late years in this country fallen into disfavour. Much discussion has been raised as to the grounds for so great a difference. It has been attributed—(1) to the type of disease having undergone a change, (2) to mere fashion or caprice; (3) to a better knowledge of the nature of disease, teaching us that its processes were of a lowering or depressing character, which were to be overcome, not by the abstraction of blood, but rather by the use of stimulants and support. It is highly probable that several causes have contributed to the undoubted change which has taken place. The year 1830 and subsequent years were marked by the epidemic visitation of cholera and of influenza. These diseases were characterized by extreme depression. If antiphlogistic measures were adopted, they proved failures, and taught the physician that blood-letting was not the universal panacea it was supposed to be. By degrees it ceased to be practised as it used to be. A new generation which knew not the past has sprung up; and, as in all reactionary movements, the practice has become at length as limited as it formerly was universal. It is almost certain that in either extreme there is an evil, and that we may have recourse in certain cases to abstraction of blood with some degree of that success which formerly led to its extensive use, if not its abuse. It will be well to consider the subject at some little length, and under the following heads:—

1. The effect of moderate losses of blood on the healthy economy.

2. The value of bleeding as a remedy in disease, together with the indications for its employment in various affections.

3. The method of performing the operations of opening an artery—arteriotomy; and opening a vein—phlebotomy.

1. *EFFECTS.*—We have first, then, to consider the effect of moderate losses of blood upon the healthy economy. Upon this point we have abundant evidence, for the custom of regularly bleeding healthy people had reached such a point during the earlier half of this century that in country districts it became a practice for adults to be bled as regularly as they went to market. No better testimony regarding the effects of this practice could be adduced than that of Sir James Paget, who, when referring to these customary venesections, says: 'I can regard those as a series of venesections fairly performed for the determination of what is the influence of the removal of blood up to the point of syncope upon a comparatively healthy person. I think I can say surely that not one of these persons suffered harm' To this might be added other and abundant testimony to the harmlessness of venesection on the healthy economy.

2. *INDICATIONS AND USES.*—Concluding, then, that the abstraction of a limited quantity of blood has no deleterious effect upon the healthy organism, we will next set forth the general indications for the use of bleeding in disease, and briefly refer to the various affections in which it may most suitably be employed.

Broadly stated it may be said that bleeding is indicated when there is evidence of marked over-distension either of the arterial or of the venous system. In either case the result will be cardiac distension—in the former case of the left, and in the latter of the right chambers of the heart. In such conditions general bleeding restores the lost equilibrium of the vascular system, and relieves the heart and the other parts concerned in the circulation of the blood.

The arterial system may be in a state of augmented tension from two causes: (1) contraction of the arteries (the smaller vessels) themselves with a diminished amount of blood in the arterial system; and (2) engorgement or distension of the arteries from spasm of the arterioles: both may be regarded as vaso-constrictive neuroses. In the first case there may be engorgement of the venous system and embarrassment of the right heart, calling for abstraction of blood by *venesection*; or visceral fluxion, the skin being pale; and in the second, relative emptiness of the veins with overfulness of the larger arteries, calling for blood-letting by *arteriotomy*.

In the former condition there would be, in *bad-side* language, a *small* hard or wiry pulse, and in the latter a *full* and hard or bounding pulse. In the former the surface of the body may present one of the two following conditions: either the skin is injected and, perhaps, dusky, and this appears to be the case ordinarily; or it is pale and cool, the blood having receded inwardly, chiefly to the abdominal viscera. The second condition obtains and is well seen in

cases of uræmic asthma, when the arterial system is turgid almost to bursting, while the veins are comparatively empty. 'Hardness' of the pulse is usually said to be an indication for bleeding, and in certain associations it is so; but it is necessary to discriminate carefully between the 'hardness' due to 'tension' of the sound artery arising from (a) excessive contraction (the small, hard, wiry pulse), and (b) overfulness (the full, bounding pulse) on the one hand; and that due to arterial degeneration with more or less hard deposit in the walls of the vessels, on the other. In doubtful cases inquiry should be made into the state of the brachial artery at the bend of the elbow. This can readily be done by flexing the limb, when, if calcareous degeneration have taken place, the vessel will be thrown into serpentine folds, visible, except in fat people, to the eye, and cord-like and rigid to the touch. The temporal artery is a less safe guide, but neither it nor an *arcus senilis* should be overlooked in this connexion. A visible and tortuous pulse in a young person may indicate aortic regurgitant disease the age of the patient must therefore be taken into consideration.

Dilatation of the arterioles would permit of the rapid passage of arterial blood into the veins under such circumstances, therefore, we should expect the blood issuing from a cut vein to present a more florid appearance than under ordinary conditions. Bleeding here should be undertaken with considerable circumspection, and not be pushed very far, for collapse out of proportion to the amount of blood abstracted might ensue. On the other hand, when there is spasm of the arterioles, and the abstraction of blood is deemed advisable, it would be well to resort to *arteriotomy* rather than *venesection*. The best guide here would be the sphygmograph, but, as few persons are yet accustomed to use it, the full, hard, bounding pulse must be relied on when found in association with corroborative symptoms.

Whatever leads to over-engorgement of either side of the heart may render bleeding necessary. If the left side of the heart be over-full, *arteriotomy* is indicated; if the right, *venesection*. The object of the withdrawal of blood from the general circulation is the direct relief of the overburdened heart. Whether the right or left chambers be taxed the immediate effect is the same; they are over-distended, and cannot get a grip upon their swollen currents. It is with the embarrassed heart as with other hollow muscular organs—the bladder and uterus. Over-distension paralyzes them by removing the 'points d'appui' essential for the initiation of muscular contraction; the energy may be there, but it cannot be exercised. It is obvious that the amount of blood which it is necessary to withdraw, in order to free the embarrassed organ, must vary considerably in different cases. But it may be safely laid down as a rule that it need rarely exceed a few ounces. Excess in this respect is the evil which formerly existed.

On this subject we may refer to the eminently practical remarks of Sir Thomas Watson, who says: 'I hold it, then, to be certain, that for some special morbid conditions, which inflammation may or may not accompany, general blood-letting, and especially *venesection*, is a potent and life-

preserving remedy, that there are many exigencies for which it is not only safe to employ, but unsafe and unpardonable to withhold it.' He also gives the following judicious advice:—

'Always it is necessary to consider the age, the sex, the general temperament and condition of the sick person, when we are turning over in our minds the expediency of abstracting blood. The very young, the old, the feeble, the cachectic, do not bear well the loss of much blood. This consideration is not to deter you from bleeding such persons ^{topically} when they are attacked by dangerous inflammation, but it especially enforces, in regard to them the golden rule that no more blood should be abstracted than seems absolutely requisite to control the disease.'

The following are some of the affections under which blood-letting would seem to be more or less indicated:—

Pneumonia.—Blood-letting in pneumonia, as in many other inflammations, is most useful in the early stages. It is indicated in healthy patients suffering from uncomplicated acute sthenic pneumonia, if they happen to be seen early enough. It relieves pain, abates fever, and if it does not arrest the disease, it certainly appears to lessen its duration. It may also be called for when there is severe pain and evidence of early embolism. It did good, and will still do good, in cases of pneumonia, attended by embarrassment of the circulation, and that in truth is the indication for bleeding in this disease.

Apoplexy.—The same may be said with reference to cerebral apoplexy. The old belief in the importance of 'letting blood' in cases of apoplexy was, if possible, stronger than in cases of pneumonia. But here again more accurate clinical and more extended pathological knowledge have taught us to look upon 'apoplexy' very differently to our forefathers. Recognising the escape of blood from the bursting of a brittle artery as a common cause of 'apoplectic fits,' we see the futility of venesection when the 'stroke' or 'fit' is due to a lesion of this kind. Nor will bleeding unstop an artery when it is plugged by an embolus, or carry nutriment to the region thus bereft of vital fluid. On the other hand we have learnt to recognise the value of bleeding in another class of cases of so-called 'apoplexy'—those which are unaccompanied by effusion of blood or lesion of the nervous tissue, but depend on rapidly occurring compression of the nervous centres from sudden or unequal increase in the volume of any portion of the cranial contents; or in certain eclamptic cases from the circulation of blood poisoned by uneliminated urinary excreta. In cases of this description, when the right heart and venous system are engorged, phlebotomy acts well; the stertor will cease, the purple face resumes its natural hue, the clouded intelligence becomes clear, and the impending danger is for the time averted. This has not cured the patient, however. It has only 'obviated the tendency to death.' It has saved the patient's life, though he may ultimately die of the disease which afflicts him. Where we meet with evidence of cerebral congestion accompanied by fullness of

the veins, a dusky countenance, and a slow full pulse, bleeding may most usefully be resorted to. In a word, although bleeding will not remove the effused blood in cases of cerebral hæmorrhage, it may sometimes be usefully employed to prevent further escape, when the heart is acting too forcibly; but it is altogether forbidden when that organ is enfeebled. The pulse at both wrists should be attentively examined before bleeding, in cases of cerebral hæmorrhage, for as a rule it is larger on the paralysed than on the sound side.

Eclampsia.—Indiscriminate bleeding in eclamptic *scizares* would be a grievous error. It would not relieve, but rather would probably intensify, convulsions of reflex origin, as in certain cases of puerperal convulsions. On the other hand, cases of puerperal convulsions accompanied by great turgescence of the vascular system, whether venous, (as is commonly the case) or arterial, would be immensely benefited by the withdrawal of blood from the general current, either by venesection or by art. riotomy, according to the indication. This treatment may serve to stop the convulsions, and though that may be far from curing the disease, it may, nevertheless, be of the utmost value, for in the first place the fits themselves may kill by their violence or frequent repetition; whilst, secondly, time may be gained for the employment of other measures calculated to relieve the oppressed system, as, for example, purging by hydragogue cathartics, vapour baths, cupping the loins, &c. This gain may be immense, for bleeding may avert impending dissolution. Moreover, permanent good may ensue, inasmuch as bleeding reduces temperature, and in the eclampsia of pregnancy the temperature is usually high. In this it contrasts with pure uræmic convulsions, in which there is lowering of temperature.

Venous Engorgement.—Engorgement of the venous system arising from chronic disease, e.g. pulmonary emphysema or heart-disease, does not call for bleeding, unless the condition be acutely intensified by some intercurrent mischief, such as acute bronchitis, for as the engorgement is slowly produced the organs and structures involved learn to accommodate themselves more or less to the altered conditions. It is only when vascular engorgement suddenly occurs in apparently healthy subjects, or, as stated above, there is acute intensification of a chronic condition, that bleeding is required. Thus, in cases where mediastinal tumours impede the return of blood from the head and upper portion of the body, the condition is ordinarily of such comparatively slow production, that bleeding is seldom urgently called for; and, moreover, it would be of but small service, for the obstruction is irremediable.

The lividity of the face which accompanies all fits should not be confounded with the duskeness due to engorgement of the venous system generally.

Uræmia.—In pure uræmia bleeding is useful; the kidneys being especially in default. For venesection answers a double purpose, by not only relieving the engorged right heart and venous system, but removing from the body a certain amount of poisoned blood—blood that is charged with urinary excreta. Doubtless, it does

good in both ways, but the former is, *quoad* the *ita*, the more important because more immediate mode of its action. The second effect, that of ridding the body of damaged blood, is obviously available to us when we have to deal with uræmia, occurring in the non-pregnant; and when coma is deepening, the heart labouring, and the vascular system turgid, no remedy is so swift and sure as the lancet.

Plethora.—Blood-letting may be called for in cases of general plethora, whether æthemic or æsthenic. In the former condition the vascular system generally seems to be overfull, though the excess is most marked in the arterial system. Arteriotomy, however, is seldom called for, though it might at first sight seem indicated, since venesection usually answers every purpose.

In æsthenic plethora, on the other hand, the venous system only is overfilled; the right side of the heart is distended and its action is laboured. Here venesection is sometimes called for, but it should be carefully employed. It is seldom necessary to withdraw more than 6 to 10 ounces of blood, and often a smaller quantity suffices.

Peritonitis.—The relief obtained by bleeding in acute peritonitis rendered venesection a famous remedy in this affection in former times. And there can be no doubt about its efficacy in relieving the pain of peritonitis, as of inflammation of other serous membranes. It may be used when the patient is young and strong, and in that stage of the disease which is accompanied by a small, hard, and wiry pulse—the pulse of a contracted artery, of augmented tension from contraction, not from overfullness. It is worse than useless in the later stages of the disease, when adynamia has set in. But valuable as bleeding may be in certain cases of peritonitis, it rarely happens that it is admissible, for in the great majority of cases inflammation of the peritoneum is secondary to other diseases, and notably to disease of the kidneys. Where peritonitis arises after delivery it is commonly of septicæmic origin, and it is seldom indeed that bleeding is of any avail under these conditions. So that, practically, bleeding is not a remedy which we can often employ in peritonitis. A very high temperature cannot alone be held to be indicative of its use for it so happens that such pyrexia is as a rule present only in septicæmic cases. Some cases of peritonitis, even fatal ones, run their course without any marked elevation of temperature: or indeed without showing any definite symptoms. Probably venesection is most serviceable in traumatic peritonitis, or it may be, when the inflammation is localised, though in that case leeches are more suitable.

Pleurisy.—When pleurisy attacks a young and robust patient, and is accompanied by severe pain, great relief follows blood-letting. The blood should be taken from a vein, and *pleno rivo*. But when, as so often happens, pleurisy is, like peritonitis, secondary to damaged blood-conditions—e.g. Bright's disease—bleeding is often inadmissible. When, as in pleuro-pneumonic cases, pleurisy complicates pneumonia, bleeding may possibly be called for, if there be great pain and oppression of the chest; but it should be most circumspectly used. Local blood-letting is much

to be preferred if bleeding be thought necessary; for general bleeding is usually incompatible with the strength of the patient.

Uræmic Asthma.—In the affection known as uræmic asthma, in which there is spasm of the systemic arterioles, with intense turgidity of the arterial system and engorgement of the left heart, bleeding, in the form of arteriotomy, appears to be clearly indicated.

Spasmodic Bronchial Asthma.—Pure asthma is doubtless often a nervous malady, and bleeding is not a remedy which should ordinarily be employed for its relief. It is only admissible when spasm of the pulmonary vessels, or obstruction to the flow of blood through them from bronchiole-spasm, leads to rapid engorgement of the right heart and venous system. This is the exact converse of uræmic asthma: but the effect in both is impediment to the aëration of the blood. Here the abstraction of a few ounces of blood from a vein may give immense and very prompt relief.

Emphysema.—It is not so, however, in the so-called 'asthmatic attacks,' which chronically emphysematous people are so prone to. Here venesection may be imperatively demanded when an acute attack of bronchitis has, by adding to the already difficult passage of blood through the lungs, excited rapid engorgement of the dilated heart and previously turgid venous system.

Interperal Diseases.—Formerly bleeding was much employed in midwifery practice, and especially in inflammatory affections after delivery. We now recognise that for the most part post-partum affections arise from septic mischief and are of an adynamic type. It is but seldom that we are called upon to bleed in these cases. Nevertheless, now and again, venesection may be called for.

Disorders of Menstruation.—Bleeding is a most valuable remedy in certain menstrual disorders, and especially in the plethora of women at the change of life. Many women suffer distressingly from general vascular disturbance at this period. The flushings, headaches, giddiness, feeling of oppression and other vaso-motor phenomena which they suffer from in association with the cessation of the catamenial flow, are immensely relieved by an occasional venesection. No other measure will so quickly and so effectually relieve these symptoms. Some robust, plethoric, amenorrhœic young women require periodical bleeding. The writer has known the abstraction of a few ounces of blood to be speedily followed by the occurrence of the menses, in cases of what may be called congestive amenorrhœa of many months' or even years' duration. It may be well to state in this connexion that in certain pulmonary, intracranial, and other visceral lesions, danger may arise from the augmented arterial tension which for a few days precedes the flow, and that the abstraction of blood may avert hemorrhage into the damaged organs.

After Operations.—Bleeding is less frequently called for in surgical than in medical practice. It is indicated mainly in the after-treatment of cases which present engorgement of the right heart and venous system, as in some cases of ovariotomy and other operations involving the ab-

sonal or thoracic cavities. A turgid venous system, with a small hard pulse, and a labouring heart—a condition which is often associated with scantiness, amounting almost to suppression, of urine—indicates blood-letting after operations of the kind above referred to.

Shock.—In certain cases of shock the abstraction of a limited amount of blood may be required. This point will be found discussed elsewhere (see *Shock*).

Fever.—That bleeding will lower the temperature of febrile patients has been known from the earliest times. It is, however, not a remedy to be resorted to for that purpose alone, for, as the most pronounced hyperrexia occurs chiefly in association with conditions leading to great depression, blood-letting is under such circumstances as useless as it is dangerous.

Insulation.—There are few disorders in which blood-letting is more successful, when rightly employed, than in sunstroke. It is seldom necessary to take more than a few ounces of blood, and excess should be particularly guarded against, for fear of subsequent collapse. The insensible patient with turgid veins, a tight pulse, and labouring heart, will gain immense and prompt relief from venesection. The extreme pulmonary congestion and over distension of the right heart so often found *post mortem* might probably be prevented by the timely abstraction of a little blood from the venous system. Bleeding is not to be thought of in the syncopeal form.

3. METHODS OF BLEEDING.—The following are the methods of performing the operations of arteriotomy and phlebotomy.

Arteriotomy.—This operation is best performed on the temporal artery. The vessel should be partially cut through by a simple transverse incision, and when a sufficient quantity of blood has been obtained it may then be completely severed, so that, retraction of both ends taking place, the hemorrhage may be arrested. A compress of dry lint should then be applied, and a tight roller-bandage applied over it.

Venesection.—The median basilic vein is the one usually selected for the operation on account of its being most readily found. The brachial artery lies immediately beneath it, and care must be taken to avoid wounding the latter vessel. The median cephalic vein is preferable, but is not so easily found. A vein on the dorsum of the foot or other part of the body may be chosen, but, as a rule, it is not desirable to open the jugular vein, especially on account of the danger of the entrance of air, and other risks.

The steps in the operation on the arm are as follows—First, the limb is to be firmly bound above the elbow by a broad tape or fillet. This should be applied with sufficient tightness to compress, and prevent the return of blood by the veins, but not so as to intercept the current in the artery, and extinguish the pulse. An oblique slit is to be made in the vessel by means of a small lancet, care being taken not to cut too deeply. The spouting blood should be caught in a vessel and measured.

When sufficient blood has been withdrawn, the operator should firmly place a thumb or a finger

on the aperture, and then, on removing compression, place upon the wound a dossil of dry lint, antiseptic dressing, styptic-colloid, or such-like, over which a roller-bandage should be twined a few times like a figure of 8, the cross being over the wound.

Local bleeding.—The object of local bleeding is the relief of congested vessels, and especially those of inflamed parts. Arteries convey more blood to, and veins convey more away from, inflamed parts; so that local bleeding may give great relief and insure resolution, since absorption does not fully commence until inflammation has ceased.

METHODS OF LOCAL BLEEDING.—Blood may be abstracted topically by leeches, by scarifications, or by wet-cupping.

1. Leeching. An average leech will abstract nearly half an ounce of blood. Leeches are extremely useful in a great variety of affections, since a pretty definite amount of blood can be withdrawn from the affected or adjacent parts, or from more distant parts, through intimacy of the vascular connexion, as in diseases of the eye and ear, and in hepatic diseases, accompanied by obstruction to the flow of blood through the portal system, when the application of leeches to the anus is most valuable.

Care should be taken not to apply leeches to parts over which sufficient compression cannot be made to control the bleeding, should any difficulty arise in arresting it otherwise. Thus, leeches should not be applied over the trachea, especially in children, in whom the error of applying them over the episternal notch is sometimes made. For the same reason the fontanelles should be avoided.

The skin of the part where leeches are to be applied should first be washed, and when they do not bite readily the part may be wetted by a little milk or sugar and milk. A slight prick of a needle, sufficient to draw a speck of blood, will often cause them to bite when refractory.

Should the bleeding continue too long after the leeches fall off, pressure or styptics may be applied. If it is desired to encourage bleeding, fomentations of hot water or linseed poultice are serviceable.

In applying leeches to the cervix uteri the precaution of closing the os by a plug of wool, should not be neglected. When applied within the mouth a leech glass should be used.

2. Scarifying.—Scarifications consist in small cuts of a depth not exceeding the eighth of an inch or less into the tissue whence it is desired to take blood. This mode of topical bleeding is mainly applied to the cervix uteri, to the tongue in acute glossitis, and to the palpebral conjunctiva in certain kinds of conjunctivitis; in the last case only slight incisions are permissible. Deeper punctures are made by some practitioners into the tissue of the cervix uteri, but these are punctures and not mere scarifications.

3. Cupping.—Cupping and the use of the scarificator constituting wet-cupping is an important method of topical blood-abstraction; and as a considerable amount of blood can thus be withdrawn, the general circulation may thereby be

affected. It is ordinarily employed, however, for its local effects.

The method of its performance is as follows:—Cupping-glasses being first put on for a brief time, as for dry-cupping (see *CUPPING—Dry-Cupping*), the operator applies to the part selected a spring scarificator so adjusted as to cut only to the required depth—about an eighth of an inch or less. The cupping-glasses are then re-applied, and the desired number of ounces of blood abstracted. If the glasses be too tightly attached the blood will not flow readily, and unnecessary pain may be caused. After their removal adhesive plaster or dry lint and a bandage should be applied to the part.

Cupping over the loins is extremely useful in renal ischæmia; on the temple or behind the ears in certain cerebral disorders, down the spinal column in inflammation of the spinal cord or meninges; and on the chest in certain pulmonary affections.

ALFRED WILTSHIRE.

BLOOD-DISEASE.—The term *blood-disease* was used by the humoral pathologists as synonymous with *dyscrasia* or *anomalous crasis of the blood*, and expressed the idea that the blood was the seat 'almost without exception' of all general diseases. And, further, since purely local disease was considered to be exceptional, the vast majority of diseases were referred to dyscrasias, and were classed under the head of blood-diseases.

The condition of the blood was considered by the humoralists to depend upon the *crasis*, that is the mixture, of its constituents, and prominent among its constituents were reckoned the *blastemata*, or germinal substances of the different tissues, which exuded through the capillary walls in the process of nutrition. When the blood-crisis was disordered or diseased, a dyscrasia was said to exist, and dyscrasias were held to be in the majority of cases primary; though it was allowed that local anomalies of nutrition might and did occasionally occur, and give rise to secondary dyscrasias. A blood-disease or dyscrasia being established, all morbid changes throughout the body were believed to be but local manifestations of the same. For the purpose, therefore, of a rational classification of diseases, a previous classification had to be made of the dyscrasias. The principal blood-crasias were said to be:—

1. The *fibrin-crisis*; including the *simple fibrin-crisis*, the *erouspus crasis*, and the *tuberculo-crisis* as varieties. The local expression of the fibrin crasis was inflammation in some form.
2. The *venous crasis*, in which fibrin was deficient. This included a vast number of special crasias, lying at the foundation of the most diverse diseases—*e.g.*, plethoria, heart-disease, acute exanthemata, rickets, albuminous urine, cholera, acute tuberculosis, lardaceous disease, cancer, acute convulsive diseases, metallic poisoning, &c.
3. The *serous crasis*; associated with anemia.

4. The *putrid or septic crasis*.

5. Anomalous crasias; such as those of syphilis, gout, &c.

The theory of dyscrasias may be said to have declined since the appearance of Virchow's

Cellular Pathology. Virchow showed that the blood is in every relation a dependent and not an independent fluid, and that the sources from which it is sustained and restored, and the exciting causes of the changes that it may suffer, lie without it and not within it. Substances may enter the blood and affect the corpuscles injuriously; the blood may act as a medium in conveying to the organs noxious substances that have reached it from various sources, or its elements may be imperfectly restored. But never is any affection of the blood itself—any 'dyscrasia'—permanent, unless new influences arise and act upon the blood through some channel or through some organ.

At the present time, while it cannot be said that humoralism is professed by many pathologists, the notion of blood-disease, as generally entertained thirty years ago, still clings to the nomenclature, and pervades some of our pathological doctrines. Diseases that affect the whole economy—syphilis, tuberculosis, gout, and cancer—are frequently described as 'constitutional,' or 'blood-diseases,' and that whether their general manifestations are secondary to local disease, as in syphilis and cancer, or are referable to inheritance. While the *morbid conditions* of the blood are real and numerous, 'blood-diseases,' so called, are but abstractions, and, as such, a fruitful source of confusion and useless discussion. It is desirable that the term *blood disease* should be abandoned, and that the expression *morbid conditions of the blood* should be applied to the pathological states of the vital fluid, which can be distinctly demonstrated by physical, chemical, or histological examination.

J. MITCHELL BRUCE.

BLOOD, Morbid Conditions of.—The characters, composition, and functions of the blood in health are sufficiently familiar, and do not require to be described here. But certain facts connected with the physiology of this fluid have a special bearing upon its pathology, and must be briefly considered before its morbid states can be profitably discussed.

A. PHYSIOLOGY OF THE BLOOD.—The *Red Corpuscles* of the blood consist of two portions—a colourless, sponge-like matrix, and a coloured substance of complex composition, which occupies the interstices of the former and accurately fills them. The matrix is regarded as possessing chiefly physical properties, while its contents constitute the active part of the corpuscle, and consist of hæmoglobin. The *source* of the red corpuscles is of the greatest pathological importance. In the embryo the blood and blood-vessels are developed from the same elements, and thus the two structures in their physiological aspect are essentially inseparable. In fully-developed blood the source of the red corpuscle is obscure; but there can be no reasonable doubt that it originates in the colourless corpuscle, and more remotely in the lymphatic glands, the spleen, and the medulla of bones; and that light is of the greatest importance in the formation of hæmoglobin. With respect to the properties and function of the red corpuscle, it is to be noted that the ultimate elements of hæmoglobin are carbon, nitrogen, hydrogen, oxygen, sulphur, and iron,

Plasma.—The physiological relations of the plasma to the organism are extremely complex; and disturbance of these relations furnishes many of the symptoms of disorder of the blood. Its mature *function* is essentially one of nutrition—it supplies the tissues with oxidisable material for development, growth, support, secretion, and the liberation of force. The *source* of the plasma is equally extensive. It derives its principal constituents from the alimentary canal through the absorbent glands and liver; while other impor-

a. *Polyhæmia*, or excess of blood in the body generally, may be the result either of excessive ingestion of the elements of blood; of the accu-

anulation of the same by the suppression of habitual hæmorrhages or fluxes; of the loss or obsolescence of a part of the body, such as a limb or a lung; or of insufficient exercise. It cannot be said, however, that polyhæmia has ever been demonstrated by exact investigation, inasmuch as the total amount of blood in the body is still uncertain, and the physiological limits in this respect are very wide. Polyhæmia is believed to be present in *plethora*, along with relative excess of the solids, and especially of the red corpuscles (see *PLETHORA*).

b. Oligæmia or deficiency of the total amount of blood is, on the contrary, an exceedingly frequent change, and constitutes the simplest form of *anæmia*. It is, however, probably never pure, inasmuch as alterations in quality appear to be inseparably associated with it; and the terms *hydræmia* and *spanæmia* have accordingly been used as synonymous with the preceding. The manner in which diminution in quantity gives rise to alteration in quality must be considered here.

When hæmorrhage occurs to any amount, and the whole quantity of blood in the vessels is reduced, the pressure falls, and absorption of the parenchymatous plasma rapidly follows; by which, along with vaso-motor stimulation, the physical relations are restored. If the loss of blood has been moderate, the only change in its composition may be considered to be *oligocythæmia*, or diminution of the red corpuscles, which alone of all the constituents of the blood cannot be rapidly restored. If the hæmorrhage has been more serious, the fluid absorbed into the circulation from the tissues, from the suppressed secretions, and from the alimentary canal, consists of water in ever-increasing excess, which carries with it an amount of salts equal to one-ninth the loss in albuminous substances. The morbid state of the blood is now beyond oligocythæmia; there is deficiency of albuminous constituents, or *hypalbuminæmia*, and the condition correctly called *anæmia* is the result. The total quantity of blood probably remains for some time below the normal. A similar impairment of the quantity, and therewith of the quality of the blood, may be slowly developed by repeated small hæmorrhages, or by any cause whatever that impoverishes the blood, whether of the nature of waste or of want. The condition which results closely resembles that just described in the acute form—oligæmia with oligocythæmia and hypalbuminæmia: the same is known clinically as *anæmia* (see *ANÆMIA*).

As a *therapeutic measure* oligæmia may be desirable. It may be induced either (1) by direct abstraction of blood, or (2) by gradual impoverishment of the blood, and reduction of the intra-vascular pressure.

2. Morbid Conditions of the Red Corpuscles.—The pathology of the red corpuscles is still imperfectly understood. The following comprise the most important changes connected with them so far as they are known.

a. Polygythæmia.—Increase in number of the red corpuscles is never considerable, being generally transitory and within physiological limits; for example, in the newly-born, and after meals. It has already been mentioned as associated

with polyhæmia in *plethora*. In the *algid* stage of cholera the red corpuscles are relatively in excess.

b. Oligocythæmia.—Diminution in number of the red corpuscles is, on the contrary, of very frequent occurrence, and of the greatest pathological importance. Microscopically the number of red corpuscles in a given visible area of blood is diminished; and chemically the amount of hæmoglobin in a given volume of blood may fall from 15 even as low as 5 per cent. The principal circumstances under which oligocythæmia occurs are—(1) in *anæmia*, or diminution in the amount of blood as a whole, from any cause, whether rapid or protracted, especially as the result of fever, the red corpuscles suffering early, seriously, and persistently, as compared with the other constituents: (2) in *leucocythæmia*—the development of the red corpuscles being interrupted: (3) in *hypalbuminæmia*, where the red corpuscles like other elements suffer from want of albuminous material: and (4) in *chlorosis*. See *HÆMAGYOMETRY*.

c. Oligochromæmia.—Deficiency of the red corpuscles in hæmoglobin has been described by this name, and is a morbid condition of the greatest possible interest, inasmuch as it is one of the essential alterations of the blood in *chlorosis*. When the individual red corpuscle contains less hæmoglobin than normal, it is said to present a pale appearance to the eye. A more trustworthy method of determining the richness of the red corpuscles in hæmoglobin, is by means of the hæmoglobinometer (see *НÆМОГЛОБИНОМЕТРЪ*). Or we may compare the amount of hæmoglobin in a given weight of blood with the number of red corpuscles in a given microscopical area. When the former is small in proportion to the latter, the defect must lie in the individual corpuscle, and this may be so great that the proportion of hæmoglobin falls, as in some cases of *chlorosis*, to 25 per cent. of the normal. See *CHLOROSIS*.

d. Aglobulism.—The effects of the two conditions of blood just described, namely, oligocythæmia and oligochromæmia, may be discussed together under the head of aglobulism, or deficiency of the blood in hæmoglobin. Want of the oxygenating substance of the organism gives rise to symptoms at once extremely various, and of the most serious import. Every vital process, whether developmental, plastic, secretory, dynamic, or nutritive, is absolutely dependent on a free and immediate supply of oxygen. All of these processes, therefore, will suffer in aglobulism. The respiratory and circulatory movements are accelerated. The complex processes of alimentation and secretion are performed imperfectly, and the results are dyspepsia, constipation, and disordered sanguification—which intensify the abnormal blood-state. Muscular contraction is feeble, and cannot be sustained. Psychical force is weak, and dulness, sleepiness, pains, and other symptoms indicate imperfect oxidation within the nervous system. Bodily growth and development—as of the sexual organs, for example—remain incomplete, and puberty is deferred. Nutrition everywhere suffers, the materials being insufficiently oxidised; and substances 'intermediate' to albumen on the one hand, and carbonic acid, water, and urea on

the other hand, are formed, especially oils. Thus the organs and the connective tissues become loaded with fat and enlarged, instead of suffering atrophy, as they do when the blood-plasma is deficient. Finally the excretions are disturbed, and the subject of aglobulism presents derangement of the colouring matters of the bile and urine, which are derived from hæmoglobin.

Histological changes.—Alterations in the size, outline, and consistence of the red corpuscle have been frequently recorded, but such accounts are incomplete, and no successful attempt has yet been made to connect any of these changes with morbid processes in the tissues. In severe fevers, such as typhus, and in some rapid malignant diseases, the red corpuscles appear peculiarly soft, their outline being less resistant and sharp, and the bodies running together into irregular heaps, instead of into *rouleaux* with well-defined lines of contact between the elements. In another class of cases the corpuscles appear small and crenated or like the 'thorn-apple.' *Macrocythæmia* and *Microcythæmia* have also been described as temporary and variable conditions, in which the red corpuscles are abnormally large and abnormally small respectively. *Transitional cells* between the white and the red corpuscle are unusually numerous in some cases of leucæmia.

3. *Changes in Colour.*—The colour of the blood is chiefly due to the red corpuscles, and alterations from the normal in this direction will be best considered in this place, although the white corpuscles and the plasma may also affect the colour, as will be presently shown.

a. The chief determining cause of the colour of the blood is the chemical condition of the hæmoglobin. When this is united with oxygen, in the arteries, the blood is *scarlet*, as deoxidation advances, this colour passes into a *purple*, and finally becomes *black* or venous. The dark colour is directly due to absence of oxygen. The purest example of this change is seen in asphyxia, where oxygen is excluded from the blood, but it also occurs as the result of the action of certain injurious influences upon the corpuscle itself, such as extreme heat, or poisoning by phosphorus, prussic acid, and other toxic agents. If the change proceed no farther, the scarlet colour may still be restored by oxidation. This blackness of the blood is generally associated with imperfect coagulation or even a state of fluidity (see *Fibrin*).

b. *Palleness* of the blood is observed in oligæmia and oligocythæmia, and is due to deficiency of the hæmoglobin.

c. The blood may be not only pale, but present streaks of a *puriform* character, even as it flows from the living vessels, as in leucocythæmia. The same blood will settle on standing into three layers—of plasma superiorly, loosely coagulated or not; of white corpuscles in the middle—a pus-like layer; and of red corpuscles at the bottom.

d. The *milky* appearance of chylous blood will be described under the head of *Blood-Plasma*.

e. *Lake blood.* The remarkable change in the blood in which it becomes lake or transparent, is frequently observed as a further stage of that first described above; but it may occur under other circumstances than deoxidation, and is of the very gravest significance, inasmuch as

it indicates complete and hopeless destruction of the red corpuscles. Lake blood is no longer opaque, but transparent; the hæmoglobin has left the corpuscles and is dissolved in the plasma. The change can be effected experimentally by the addition to blood of water, chloroform, the bile-acids, or other solvents; and it is probable that some of the cases of rapid death after enormous draughts of water, and the destruction of red corpuscles that is believed to occur in jaundice, may be accounted for in this way. But the most important cause of 'solution' of the red corpuscles is complete deoxidation of the hæmoglobin, which is followed by its diffusion in the plasma. Thus drawn blood is rendered lake by the addition of sulphide of ammonium, phosphorus, phosphoric acid, or iron-silings; and the same effect is produced by the intravenous injection of salts of the bile-acids. This being so, it might be expected that blood would assume the like appearance when exposed to the prolonged action of the causes that render it black; and recent observations seem to indicate that such is the case. In a number of diseases which are attended with the accumulation of oxidisable substances in the circulation, the blood has been described as 'fluid,' 'claret,' or 'cherry-coloured,' 'clear,' and 'staining the tissues,'—but apparently without more exact observations on the colour of the living plasma. Such diseases are high fevers, hyperpyrexia, insolation, and poisoning by malaria, phosphorus, and perhaps other agents. The effect of some of these influences is obviously to produce an excessive amount of oxidisable material in the blood, while the others may lead to the same result by reducing the oxygenating capacity of the corpuscles. Persons dying under such circumstances present great lividity, from the black or venous condition of their blood; death occurs with symptoms indicative of want of oxygen, as if so much of the hæmoglobin had been diffused through the plasma; and *post mortem* the vessels are found stained with the solution, the tissues are soaked with fluid lake blood, and decomposition is early and rapid. The 'fluidity' of, or absence of clot in such blood will be presently accounted for under *Fibrin*. That a similar solution or destruction of the red corpuscles may occur in all cases of fever, but in a much less degree, is supported by several facts:—(1) the increased discharge of potash-salts in fever; (2) a similar increase of the colouring matter of the urine; and (3) the anæmia that is found at the termination of the process.

f. Other alterations in colour may occur in the blood. The blood is *light-red* after poisoning by carbonic oxide, and remains so after exposure. It is *chocolate coloured* after poisoning by the nitrites such as nitrite of amyl; and other hues have been recorded.

4. *Melanæmia.*—In relation with the pigment-bearing element of the blood may be mentioned a morbid condition which has been described under the name of melanæmia. In it there are found in the blood black and brown pigment-particles and flakes, free or contained in cells of various shapes. This state is especially associated with two others, namely, malaria and an enlarged deeply-pigmented condition of the

spleen; and it is highly probable that the pigment-particles are produced by the fever, and find their way from the spleen into the blood. They are thus deposited in the liver and other organs, and give rise to symptoms of visceral disturbance during life, and to the peculiar slaty or grey discolouration that is found *post mortem*. It has been said that in melanotic cancer pigmented cells have been found in the living blood.

6. Morbid Conditions of the White Corpuscles.—The white corpuscles of the blood may undergo certain morbid changes both in number and appearance.

a The most remarkable of these is increase in numbers, which may advance to such a degree that the white corpuscles become as numerous as the red. This condition is known as *leucocythæmia* or *leukæmia* (see *LEUCOCYTHÆMIA*). Short of this, however, the proportion of white corpuscles in the blood may be appreciably increased, and to this minor condition the name of *leucocytosis* has been applied. *Leucocytosis*, according to Virchow, accompanies, almost unexceptionally, every case of lymphatic excitement, such as inflammation, and tubercular scrofulous, or cancerous enlargement or swelling of the glands and allied structures—Peyer's glands, the solitary follicles, the spleen, and the tonsils. *Leucocytosis* is distinguished from *leucocythæmia* by its very moderate degree, by its evanescent course; by the absence of deficiency of the red corpuscles; and by the accompanying symptoms. *Leucocytosis* may be appreciated even by the naked eye in the clot of drawn blood, by the presence of an irregular 'lymphatic layer'—*crusta lymphatica*, consisting of collections of white corpuscles between the red clot and the buffy coat which so frequently occurs along with it.

b A *diminution* in the number of white corpuscles occurs in chlorosis, and, it is said, in malaria, especially during the paroxysm of fever.

c With regard to the *structure* of the individual white corpuscles, the proportion of uninnucleated or young cells, and of multinucleated or aged cells may be disturbed both in *leucocytosis* and *leucocythæmia*; while corpuscles may be found containing granules of various kinds, especially pigment-particles, bacteria, micrococci, and other structures.

6. Morbid Conditions of the Blood-plasma.

—(1) *Water*.—The limits of the physiological variations in the amount of water in the blood are very wide.

a *Diminution* of water in the blood is observed in various degrees. It is moderate and transitory as the result of stimulation of the kidneys, skin, or bowels, but the normal proportion is speedily restored by absorption. This condition is found after severe purgation, sweating, diarrhœa, or dysentery; and its production is the rationale of several of the methods adopted for the relief of dropsy. If the drain of water continue, or if the supply fail, the anhydric condition of blood increases, so that the fluid appears black, thick, and tarry. Such is the state of the blood in the algid stage of cholera; the specific gravity of the serum rising as high as 1.080, accompanied by a comparative excess of salts, albumen, and urea. The chief symptoms of great deficiency of water in the blood are intense thirst; a shrivelled shrunken

aspect of the body generally; coldness and lividity of the extremities; muscular pains; and suppression of the excretions—phenomena directly referable to loss of water, retardation of the circulation, and interference with the function of the red corpuscles.

b *Excess*.—*Hydræmia*.—Reference has been already made under the head of oligæmia to the anæmia or hydræmia that follows it. Excess of water in the blood is perhaps never absolute, and the change may therefore be regarded with equal accuracy and greater convenience as deficiency of solids.

(2) *ALBUMINOUS CONSTITUENTS*.—On reviewing what has already been said under the head of Coagulation and Fibrin, the reader will observe that 'amount of fibrin,' and other expressions connected with the albuminous constituents, must be regarded at present as comparatively meaningless, in the light of our knowledge of the process of coagulation. Inasmuch, therefore, as little value can now be attached to the analyses of fibrin that have been made in different diseases, it follows that the estimates of the albuminous substances left after coagulation—that is, of the albumins of the serum, must also be rejected. But the total amount of albumin in the blood may be easily ascertained, and this is subject to extensive variations. The balance between the albuminous substances, which enter the blood from the alimentary tract and the lymphatic system, on the one hand, and the products of their transformation by the tissues, on the other, is represented by the albumins of the blood. These will increase accordingly when the supply is excessive, or the consumption small, and will decrease under opposite circumstances.

a *Hyperalbuminosis* is the name given to excess of albumin in the blood. The amount has been found notably increased when the activity of the tissues is abnormally heightened, as for example in inflammatory diseases (acute rheumatism, tonsillitis, pneumonia, and pleurisy); and when fibrinogen, which is the product of this increased activity, is poured abundantly into the blood. The amount of albuminous fluid produced in an inflamed part, whether it appears as a catarrh, an infiltration, an exudation, or an effusion, is very great, and may be enormous; and, under favourable circumstances, this and much that cannot be so easily appreciated is carried into the blood, the lymphatic structures swelling *en route*. *Hyperalbuminosis* as a result of diminished consumption probably does not exist; for the effect of an insufficient supply of oxygen to the albumins—(want of exercise or over-feeding)—is not the accumulation of these in the blood, but the formation of 'lower' products, such as uric acid and its allies, and the deposit of fat. Relative hyperalbuminosis is a necessary but transient effect of cholera and other severe watery fluxes.

b *Hypoalbuminosis*, or *deficiency* of albumin in the blood, occurs under exactly opposite circumstances from the preceding,—whether the ingestion of albumin from the alimentary tract and the tissues be comparatively small, or the consumption excessive. Inanition, therefore, on the one hand, and its multitude of causes, are associated with such poverty of blood; and so, on

the other hand, are loss of blood, profuse discharges of albuminous fluids, morbid growths, and other sources of waste, as well as excessive demands of growth and development. The albumins of the plasma may fall under these circumstances from 80 to 37 parts in 1,000. Such hypalbuminosis is, however, never simple: the blood cannot be deficient in albuminous substances and otherwise normal, for, as we have already shown, loss of albumen is always followed by absorption of water and salts from the tissues in definite proportions, and anemia is the result. The red corpuscles suffer at the same time, for their nutritive supply fails in hypalbuminosis, and aglobulism ensues. Hypalbuminosis is thus a serious disease of the blood. The relations of these conditions to each other and to oligæmia are even more complicated clinically than they are pathologically, and in this relation the whole of them are most conveniently discussed under the comprehensive head of anemia (*see* ANÆMIA).

(3) **Clot, Fibrin.** However uncertain as a measure of any particular constituent in the blood, the amount of clot or fibrin demands a brief notice as a matter of fact.

a. Abundant clot has been considered as indicating an excess of fibrin in the blood or *hyperinosis*, the proportion being stated to rise as high as 1.0 instead of 0.2 per cent. Acute rheumatism, cellulitis, pneumonia, and pleurisy are the diseases in which hyperinosis is most marked, but it also occurs in pregnancy. The two principal conditions of its occurrence appear to be—(1) Increased activity of the tissues—including inflammation, and (2) Free and abundant communication of these tissues with the blood through the lymphatic system.

b. Deficiency, looseness, or absence of clot—‘*Fluid blood*.’—A small loose clot is frequently observed, as for example in typhoid states, or in chronic wasting diseases attended with loss of blood, and has been described as indicating *hypo-inosis* or deficiency of fibrin. When the condition is extreme, the clot may be absolutely wanting, as in certain cases of anemia the blood then separates on standing into three layers—an upper, consisting of clear liquid, a middle, puriform, of white corpuscles, and a lower, red, of red corpuscles. In another and larger group of cases, non-coagulating or fluid blood is at the same time of an intensely dark colour or even like and is commonly described as ‘black.’ The circumstances under which this condition of blood occurs, and the cause of the remarkable colour have been already noticed; and it remains to account only for the fluidity. The profound alteration of the red corpuscles, the want of oxygen, the interference with the production of the ferment, and the changes in the fibrinogen and fibrinoplastic substance—one and all combine to prevent coagulation.

c. Buffy coat. Another phenomenon connected with coagulation, from which erroneous and even dangerous conclusions have been drawn, is the so-called *buffy coat*. The process of coagulation is generally sufficiently slow to allow of the gravitation of some of the red corpuscles from the surface of the blood; and the corresponding part of the clot is accordingly paler. When the

pale layer is unusually large it is known as the *buffy coat* or *crusta phlogistica*: it may be seen in the blood in pregnancy, inflammatory fevers, h; iremia, and oligocythæmia. When these cases are analysed, it is found that the conditions favourable to the formation of the *buffy coat* are probably all more or less connected with the red corpuscles, namely—(1) increased specific-gravity of the red corpuscles, as in oligocythæmia and hydremia—allowing more rapid sinking; (2) interference with the catalytic action of the hæmoglobin, which is so powerful in determining the rapidity of coagulation, as in fevers and oligocythæmia; and (3) want of oxygen, corresponding to the amount and condition of the hæmoglobin, as in the same diseases. One and all of these states render the process of coagulation slow compared with the descent of the red corpuscles; and the *buffy coat* is the result. It thus appears that the *buffy coat* is no indication whatever of excess of fibrin-generators, or of the opposite, and that it is found under the most diverse conditions of blood.

(4) **Salts.**—The amount of positive knowledge concerning morbid alterations of the salts of the blood is but small. It is to be observed that the salts of the plasma have chiefly sodium as their base, while potassium-salts mostly reside in the corpuscles.

a. Diminution.—In febrile diseases there is an increased discharge of compounds of both bases, but at different periods, the potassium-salts appearing in excess in the excretions until the crisis is past, and the sodium-salts during deconvalescence. At both periods, it may be considered certain that the blood is the chief source of the salts excreted, and that it is accordingly deficient in these constituents.

b. Excess.—On the other hand, the salts of the plasma are relatively in excess in hypalbuminosis, replacing, in the proportion already stated, the lost albumen. The effect on the salts of the blood of such drains as occur in cholera has been variously stated, some authorities declaring that it is an increase, others a diminution.

c. Reaction.—The alkalinity of the blood is said to be diminished in gout, cholera, and osteomalachia.

(5) **Fats.**—The normal increase of fats in the plasma that occurs after meals may be exaggerated by a diet rich in oil, and it is said, in chronic drunkards and in persons disposed to obesity. When this increase is so great that the serum presents a milky appearance the blood has been called *chylous*. A cream-like scum forms on the surface of the serum; and the milky appearance is found microscopically to be due to the presence of fine granules and oil-globules. A marked increase of fatty matters in the blood has been found in some cases of chyluria. Fat may also appear in the blood as a foreign body, by the escape of marrow into the circulation in fracture of bones—and that in such quantity as to cause fatal capillary embolism.

(6) **CARBONIC ACID**, which exists in arterial blood in the proportion of 30 per cent., and in venous blood of 35 per cent., by volume, may accumulate within the circulation either by increased formation or by retention. Although associated with asphyxia, this increase of carbonic acid is

probably not the cause either of the symptoms of that condition, or of the dark colour of the blood that accompanies it.

(7) **OTHER CONSTITUENTS.**—Amongst the most important of the other constituents of the blood, the following are to be noticed:—

a. *Urea*, which exists in normal blood to the amount of 1·8 parts in 10,000, may increase in uræmia by two or three times. There is still much uncertainty, however, on this subject (see *URÆMIA*). Disease of the urinary organs, which interferes with the elimination of urea and allied products from the blood, is the usual cause of uræmia; but excessive tissue-change, as in fever and inordinate muscular exercise, has also the same effect.

b. *Uric acid*, found in normal blood in minute traces, is increased (as urate of soda) in all cases of gout, and may amount, according to Dr Garrod, even to 0·175 parts in 10,000. Its presence is easily demonstrated by the thread-experiment (see *GOUT*). Uric acid is also increased in leukaemia and chlorosis—probably from the imperfect oxidation associated with the condition of the red corpuscles.

c. *Leucin*, *tyrosin*, *hippuric acid*, *sarcin*, and other allied complex compounds, have been frequently found in the blood in small quantities, and the same may be said of *oxalic* and *lactic acids*, and of *acetone*.

d. *Bile*.—Certain of the constituents of the bile may occur in the plasma. The most obvious of these are the *bile-pigments*—*biliverdin* and *biliverdin*, which either by direct formation in the blood from the hæmoglobin, or more frequently by absorption from the liver, accumulate within the circulation, and by their deposit give rise to the colour of the tissues in jaundice. The *bile-acids*—*glycocholic* and *taurocholic acids*—are also under certain circumstances absorbed into the blood, where they may be detected with difficulty. They have a destructive effect upon the red corpuscles, and act further as a powerful poison to the tissues, causing the excessively severe symptoms that may occur in hepatogenous jaundice. *Cholenteria* is credited by some pathologists with being the cause of the same symptoms, and it has been found in the blood in increased proportion in some cases of severe jaundice.

e. *Sugar*.—The sugar of the blood is increased in diabetes, in some cases reaching 0·3 to 0·5 per cent.

7. **Extraneous Matters in the Blood.**—Besides its normal constituents and their products, the blood may occasionally contain certain matters entirely foreign to it such as the numerous poisons which act either directly upon the corpuscles, or remotely upon the organism. These, entering the circulation before they exert their specific effect, are in many instances readily discovered by analysis. The acid compounds of hydrogen with sulphur, phosphorus, arsenic, and antimony, respectively, act as blood-poisons by depriving the oxyhæmoglobin of its oxygen; while carbonic oxide and nitrous oxide unite with the hæmoglobin, and expel the oxygen from the blood. It is a matter of speculation whether other so-called poisons, the nature of which is still obscure, do not enter the blood and there exert their primary effect, such as the contagium of acute

specific fevers and other infectious disorders. Similar infective matters, produced in the tissues of the body itself, are believed to be absorbed in septicæmia, pyæmia and other allied diseases, and numerous observations support the further belief that the presence of *bacteria* is intimately associated therewith. A somewhat similar infection may occur in malignant disease, the juices being mixed with the blood-plasma, but in some instances the process may be different, namely by means of cells. We cannot expect to detect these cells in the blood *in transitu*. The same remark applies to emboli,* of whatever nature and to blood-crystals.

8. **Organisms.**—The blood may contain a variety of living organisms, either foreign or peculiar to itself; the latter being called *hematozoa*. See *HEMATOZOA*, *CHYTRIDIA*, and *REINING FEVER*; also *BACTERIA*, *FIARIA SANGUINIS-HOMINIS*, *MICROCOCCI*, *SPIRITUM*, and *ZYMÆ*. J. MITCHELL BRICE.

BLOOD. Transfusion of. See *TRANSFUSION*.

BLOOD-WORMS.—This term is of general application. It refers to all kinds of Entozoa living in the blood. See *Hæmatozoa*.

BLUE DISEASE. A condition in which the most prominent symptom is a peculiar discolouration of the skin and mucous membranes, due to the circulation of dark blood in the vessels. See *CYANOSIS*, and *HEART*, *Malformations of*.

BOILS.—SYNON.: Furuncles; Fr. *Furoncle*; Ger. *Furunkel*.

DEFINITION.—Gangrenous inflammation of the skin, forming small painful swellings, and ending by expulsion of the necrosed centre or 'core'. The inflammation begins in the glandular structures, hence involving not only the skin, but also the cellular tissue immediately beneath. The sebaceous glands are most commonly the seat of boils, but occasionally the Meibomian glands (*stye*), the ceruminous glands, and the sweat-glands of the armpit, or, more rarely still, the glands of the lips, vulva, or anus are affected.

ÆTIOLOGY.—The predisposing causes of boils are—the male sex, middle life; a stout habit of body, seasons of spring and autumn; a diet too full of flesh, or one suddenly changed, such as that adopted during training for rowing, &c. To these must be added the vitiation of the blood during exhausting fevers and in certain cases of saccharine urine, or induced by inhaling dissecting-room effluvia; and dirty occupations, for example, chimney-sweeping or rag-picking. Lastly, boils are sometimes epidemic.

Local causes.—The parts of the skin most exposed to dirt or chafing, the hands and face, the neck and back, the buttocks and knees, are favourite sites for boils; but they may form on any part except the palms and soles. Blisters, poultices, and stimulating liniments occasionally cause them.

To these causes is added by some authors the specific contagion of a parasitic fungoid plant, the mycelium of which by developing in a gland-cell, thereby causes limited necrosis (the slough) of the tissue in which it grows. The truth of this view is not yet clearly established.

SYMPTOMS.—Boils appear either singly, in succession, or several at once, forming then as

eruption on the skin. The solitary boil begins with itching; soon a reddish pimple forms, sometimes tipped with a minute vesicle, in the centre of which a hair may generally be detected. The pimple grows larger and harder, the red area increases and grows darker, and pain begins, stinging at first, then throbbing. In about five days the summit breaks, pus oozes forth, the pain abates, and the hardness diminishes. A day or two later the core, a shred of sphacelated cellular tissue, escapes. The boil then subsides, and healing rapidly takes place; the scar is depressed, and for some time of a violet colour. Occasionally the inflammation affects chiefly the cellular tissue beneath the skin; the mass is then softer, more round and clearly circumscribed, and fluctuates like an abscess—this variety forms in the armpit. Rarely, the central slough extends rapidly beneath the surface, and communicates with the surface by several small apertures (*carbuncle*). In other cases the swelling is more diffuse, no core appears at the surface, but a hard very painful pimple is formed, which is long in subsiding (*blind boil*). The furuncular eruption, consisting of groups of small boils, forms successive crops, and thus the disease may continue a long time. Boils are generally limited to a small region, but this is not always the case, and the greater part, even the whole, of the body may be attacked.

The constitutional disturbance is usually *not* or slight when the boil is due to local irritation, though it may suffice to render nervous, irritable persons unfit for work. When the boils are caused by exhaustion, the general symptoms are severe and denote great depression. Prostration, agitation, stupor, low delirium, dry brown tongue, urdes, vomiting, and diarrhoea set in, and the case often ends fatally, or recovery is very slow, accompanied by much suppuration. Septic absorption and pyæmia very rarely take place.

Carbuncular Boil of the Face.—There is a rare and often fatal form of boil, the determining cause of which is unknown. It is met with only on the head and neck, notably on the lip. Mild and trifling at first, like an ordinary boil, it rapidly extends by inflammation of the veins or lymphatics, and causes poisoning of the blood. The earliest sign of this fatal change is the occurrence of violent and repeated shivers. The boil becomes a boggy swelling of blackish violet colour; the surrounding tissues become hard and brawny; suppuration ceases; sloughing occurs; the complexion grows earthy, the features, if the boil is on the face, become everted; the skin round the eyes in some cases is puffed out, and the eyes themselves project from the sockets; anxiety and laboured gasping breathing set in; and a violent constricting pain in the head, chest, or belly is frequently experienced. Delirium and coma usually supervene, but sometimes consciousness and terrible suffering remain to the last. The duration from the first shiver to the end is about four days. The veins of the face first inflame, and the phlebitis extends by the veins of the orbit to the sinuses in the skull, to the diploe, &c.; hence abscesses form in the eyelid, the forehead, the meninges, or the brain, and occasionally in distant viscera.

DIAGNOSIS.—A boil is distinguished by the

central cavity and slough—characters peculiar to it. The boil of the face accompanied with phlebitis has been confounded in this country with the 'malignant pustule' of Continental surgeons. The former is still a *boil* with a central core. The '*pustule maligne*' is said to have invariably a large vessel surmounting a brownish ecchyma, with a ring of smaller vessels round the larger one,—a condition never met with in boils.

PROGNOSIS.—When due to local causes, the prognosis is always good, unless the patient be exhausted by old age or fever, under such circumstances the extensive sloughing and suppuration often lead to a fatal issue.

TREATMENT.—General.—First remove predisposing causes, and invigorate the patient by change of air, outdoor exercise, vapour and Turkish baths. The diet should be moderate and mixed. Alcohol, unless the patient is greatly debilitated, should be given in very moderate quantity, and the form of fermented liquor most habitual to the patient is best. Much alcohol taken before the core has loosened increases the pain and throbbing. Occasionally a saline purge should be given. Of empirical remedies, yeast (a tablespoonful three daily) is said to put an end to the repetition of boils. Quinine and perchloride of iron are also used. Quinine should be given to an adult in five-grain doses every six hours, till ringing in the ears and headache begin; it should then be gradually lowered for three or four days to three or four grains per diem, and then left off. In obstinate cases the waters of Vichy, Barèges, or Harrogate are believed to remove the disposition to boils. In diabetes omission of sugar-forming food, and the free administration of alkalis are the most effectual remedies. For the exhausting boil of the face, large doses of brandy, with quinine, are required.

Local.—When signalled by itching, a boil may be stopped by plucking out the hair of the inflamed follicle, and in a long succession many boils may thus be prevented. When the areola has formed, if the pain be slight a drop of caustic solution applied to the centre will sometimes check the progress of the boil. A better plan at this stage is to cover the boil with a gullumum and opium plaster (Erasmus Wilson's) spread on leather. Under this treatment pain at once ceases, the inflammation gradually subsides, and the separation of the core proceeds painlessly; when the boil discharges, a hole should be cut in the centre of the plaster, for the escape of the products. When the pain is stinging, and the areola wide, with restlessness and headache, warm poultices are most soothing—those of starch cause pustulation less than linseed meal poultices. Mixing lard with linseed poultice, or sprinkling it with the dilute solution of acetate of lead, has a similar effect. Poultices hasten the expulsion of the slough, but should be discontinued as soon as the hardness changes to doughiness. If the slough is large, the surface may be dressed with lint spread with Paravian balsam, and the boil carefully protected by means of pads and compresses.

Incisions are now much less employed than formerly. They increase rather than lessen the loss of tissue in ordinary boils, and do not

shorten the duration of the inflammation. They give relief to pain, however, and check the spread of diffused boils. When made, incisions should be free, crucial, or even star-like, and carried beyond the boil. In the rapidly extending boil of the face local treatment is of little avail; the free use of the actual cautery may be beneficial if employed at an early period.

BRECKLEY HILL.

BONE, Diseases of.—Under this head are included:—Acute and Chronic Inflammation of bone and its membranes, with the consequences thereof, such as Caries, Necrosis, and Abscess, New Growths which arise both within and upon the bone; Malformations; and certain Disorders of Nutrition, namely, Hypertrophy and Atrophy. Bone-tissue should be regarded as being similar to other connective tissues, but some diseases affecting it are rendered obscure, while others are materially modified, by reason of its meshes being filled with lime-salts.

1. **Inflammation.**—As a matter of clinical convenience, it is usual to consider separately inflammations of the periosteum, of the bone proper, and of the medulla, but it should not be forgotten that these structures are throughout continuous and interdependent, and that disease is rarely exclusively confined to any one of them—it may originate or be chiefly developed in one, but it cannot long exist without involving the others to a greater or less degree.

A. **Periostitis**—*Inflammation of the investing membrane of bone (die Knochenhaut).* By periosteum is usually meant the thin fibrous envelope of the bone in which the vessels for the supply of blood subdivide. But between it and the bone is a layer of osteogenetic cells like the cambium-layer of a growing plant, and immediately external is a layer of cellular tissue, continuous with that of the adjacent parts, these are integral portions of the periosteum, and take an active share in all its diseased processes. Periostitis may be either *acute or chronic*.

(a) **Acute periostitis, osteoperiostitis, acute pyriosteal abscess, or acute necrosis.**—This is a formidable, but fortunately comparatively rare, disease, at least in the adult. It attacks the long bones almost exclusively, usually those of delicate children or young adults, in whom active bone-growth is still going on, and the periosteum is highly vascular. Acute periostitis probably never occurs without coincident inflammation of bone, and it is by far the most common cause of necrosis. It will be best to regard it as an acute osteitis and periostitis combined, and to call it *osteoperiostitis*, just as we call inflammation of the bone and of the endosteum *osteomyelitis*. The extent to which the bone and the periosteum are in the first instance respectively involved is always difficult, and sometimes impossible, to determine—it may be inferred from the extent of the necrosis. There are two ways in which the disease may begin—either in the fibrous investing sheath of the bone and the cellular layers beneath and superficial to it, from whence it spreads inwards to the cortical bone-substance, or even to the medulla; or in the bone-tissue—the inflammation spreading outwards to the periosteum. It is impossible

in the living subject to distinguish acute osteomyelitis and osteoperiostitis arising from idiopathic causes. The disease is usually attributed to an injury, often slight, or to exposure to extremes of cold or heat. Frequently no cause is assignable.

PATHOLOGY.—Rapid exudation takes place in the layers of the periosteum, and in the Haversian spaces and canals of the bone, to such an extent as to obstruct the circulation, and probably to cause by pressure the severe pain complained of at the outset. The exudation beneath the fibrous layer of periosteum is copious, and soon becomes purulent, the periosteum is detached; the vascular supply of the bone is cut off, and necrosis results. The extent of the necrosis depends upon the extent to which the periosteum is engaged, while the thickness of the dead bone depends mainly on the depth to which the inflammation in the osseous tissue extends. Large accumulations of pus are often rapidly formed in these cases, the pus escaping through openings in the fibrous envelope into the circumjacent cellular tissue. The shafts of the tibia and femur are the parts most frequently affected, the disease occurs more rarely in the bones of the upper extremities and other parts of the skeleton.

SYMPTOMS.—One of the earliest symptoms of acute periostitis is sudden and severe pain in the affected bone, which is soon followed by intense fever. On the second or third day deep-seated swelling sets in, somewhat obscure at first. After an interval varying from five to ten days, the inflammatory signs approach the surface, the skin becomes edematous, pits on pressure, and finally reddens and inflames. The length of interval depends on the thickness of muscles and soft parts covering the affected bone. Other things being alike in respect of pain and amount of fever, the longer the delay in the appearance of external swelling, the greater the probability that the bone is the first and chief tissue engaged, the inflammation having reached the periosteum secondarily, while the early appearance of swelling and fluctuation externally suggest that the inflammation is chiefly periosteal. Blood-poisoning, either septicæmic or pyæmic, is a common consequence of acute inflammation of bone and periosteum.

DIAGNOSIS.—This disease may be obscure at the commencement, and its nature overlooked; it has often been mistaken for acute rheumatism on account of the swollen joints, for phlegmonous erysipelas, for acute cellulitis, or for typhoid fever. The only malady with which acute periostitis need be confounded is an idiopathic inflammation of the deep-seated cellular tissue in a limb. This disease is rare. When we observe the chain of symptoms above described in a young person, we may safely assume the presence of an acute osteoperiostitis. The disease almost invariably terminates in suppuration and necrosis; resolution happens rarely, but necrosis is not inevitable, even after suppuration. In a few cases, especially in young children, if the matter be speedily evacuated, the abscess collapses, the periosteum reunites with the bone, and no necrosis takes place. This result is unfortunately quite exceptional.

PROGNOSIS.—This must be founded on the

extent of the necrosis; whether blood-poisoning has taken place; and whether the adjacent joints are implicated in the disease. Cure cannot take place until the dead bone is cut off or removed, and this is often long delayed. The usefulness of a limb may be permanently impaired by the disease, or it may require amputation, or the patient may lose his life altogether. On the other hand, the use of the limb, and the health of the patient, may become completely re-established.

TREATMENT.—Early and energetic treatment is of the greatest importance, as it affords the best prospect of averting the disastrous consequences of acute periostitis, but in hospital practice the cases are rarely seen sufficiently early. In the first stage the limb should be elevated, and ice applied; painting the limb with a strong solution of iodine is advisable. As soon as the nature of the affection is manifest, incisions down to the bone, so as to divide the periosteum, are indicated even before pus is formed. They relieve pain and tension, and, by permitting the timely escape of pus as soon as it does form, the amount of periosteal separation, and consequently of necrosis, is limited. It is the more important to make an early incision, because evidence of fluctuation is at first by no means clear or easy to make out, and this should, therefore, be done in all cases of doubt. Antiseptic precautions should always be taken. Sometimes the abscess cavity does not readily collapse, owing to its walls being stiff and infiltrated, and its contents may become putrid, thus greatly increasing the patient's risks. If there be synovial effusion into a neighbouring joint, the limb should be kept at rest by means of a splint or a fixed bandage. When the acute symptoms subside, the abscess-cavity contracts, one or more sinuses remain, and the dead bone begins to separate (see *Necrosis*).

Where the epiphysis is engaged in the disease the case is more urgent, the fever runs higher, the suppuration is greater, and the degree of joint-implication more intense, proceeding in extreme cases to suppurative inflammation and destruction of the articulation. The oedema of the limb often indicates a deep-seated phlebitis, the precursor of septic poisoning. Under these circumstances, amputation of the limb is often the only resource. It is imperative to amputate where there is extensive bone-destruction, and the symptoms indicate commencing pyæmia, or where, with the death of a large portion of the shaft, one or both of the neighbouring joints has become gravely implicated, and great suffering and loss of strength forbid us to temporise. It is precisely in these cases, however, where the epiphysis has become increased up to the epiphyseal junction, that good results are attainable by the immediate extraction of the dead bone. The shaft where it joins the epiphysis becomes rapidly detached and loose, and may easily be separated, while the bone can be divided with a chain saw beyond the limit of the necrosis in the other direction, and removed. It is difficult, however, in the early stages to diagnose the extent of the necrosis. Where the joints both above and below are involved, amputation is usually necessary.

A periostitis of a very acute form, almost

invariably suppurating, and accompanied by necrosis, is very common in the fingers, where it chiefly affects the ungual phalanges. The pain is very great, but may be relieved by an early and free incision down to the bone, which, nevertheless, does not usually avert either suppuration or necrosis.

(b) *Chronic periostitis* is usually due to some diathetic cause, but may result from injury, or from some continuous pressure. It is most frequent on the superficial parts of the skeleton, as the tibia, clavicle, skull, and ribs, but may affect any bone; and it is often observed at the origin or insertion of muscles. When the disease arises from a general cause, such as syphilis, many parts of the skeleton are affected; when from a local cause, usually only one.

SYMPTOMS.—Chronic periostitis generally takes the form of what is called a *node*—a tender, more or less painful, rounded or oval swelling, at first tense and hard, afterwards softer, or even fluctuating. The pain is much greater at the outset, from the tension of the parts involved, and is generally worse at night. Subsequently the swelling becomes indolent, and painless, unless pressed upon. Nodes are due to a localised inflammation. The cambium-layer of the periosteum and its external layer proliferate and become filled with leucocytes, thus forming a well-marked projection on the bone, which may undergo resolution, suppurate, or ossify, according to circumstances.

PROGNOSIS.—In chronic periostitis this is usually favourable. Under the influence of early and suitable treatment, the inflammatory products are completely absorbed, and the bone resumes its natural shape. If the chronic inflammation of the periosteum be permitted to proceed unchecked, a deposit of new osseous lamellæ usually takes place on the surface of the affected bone, giving rise to permanent thickenings, or even to osteophytic growths. These are composed of light porous bone, with a rough surface. The skeleton of a syphilitic subject will often present numerous thickenings of this nature. On making a section of the bone, it is easy to see that the new bone is superimposed upon the old, and is formed by the periosteum.

TREATMENT.—When due to a local cause, the swelling will often spontaneously subside with rest to the part, but in obstinate cases iodide of potassium internally, and iodine ointment or blistering externally, may be required. If the subject be unhealthy, or if the original injury be considerable, suppuration may take place, when the treatment will be that of an *inflammatory abscess*. *Syphilitic nodes*, which are a very common expression of chronic periostitis, yield rapidly to the influence of iodide of potassium, which in some cases may usefully be combined with a mercurial course. Blistering or friction externally is hurtful in such cases. Syphilitic nodes are not at first prone to suppuration, and even when they become soft and fluctuating, and the skin reddens over them, they should not be mistaken for abscesses, as they readily become absorbed under suitable treatment.

(c) *Periostitis after typhoid fever*.—A peculiar form of chronic periostitis is occasionally observed as a sequel to typhoid fever. It occurs during

shorten the duration of the inflammation. They give relief to pain, however, and check the spread of diffused boils. When made, incisions should be free, crucial, or even star-like, and carried beyond the boil. In the rapidly extending boil of the face local treatment is of little avail; the free use of the actual cautery may be beneficial if employed at an early period.

If there be synovial effusion into a neighbouring joint, the limb should be kept at rest by means of a splint or a fixed bandage. When the acute symptoms subside, the abscess-cavity contracts, one or more sinuses remain, and the dead bone begins to separate (*see Necrosis*).

Where the epiphysis is engaged in the disease the case is more urgent; the fever runs higher, the suppuration is greater, and the degree of joint-implication more intense, proceeding in extreme cases to suppurative inflammation and destruction of the articulation. The oedema of the limb often indicates a deep-seated phlebitis, the precursor of septic poisoning. Under these circumstances, amputation of the limb is often the only resource. It is imperative to amputate where there is extensive bone-destruction, and the symptoms indicate commencing pyæmia; or where, with the death of a large portion of the shaft, one or both of the neighbouring joints has become gravely implicated, and great suffering and loss of strength forbid us to temporise. It is precisely in these cases, however, where the diaphysis has become increased up to the epiphyseal junction, that good results are attainable by the immediate extraction of the dead bone. The shaft where it joins the epiphysis becomes rapidly detached and loose, and may easily be separated, while the bone can be divided with a chain saw beyond the limit of the necrosis in the other direction, and removed. It is difficult, however, in the early stages to diagnose the extent of the necrosis. Where the joints both above and below are involved, amputation is usually necessary.

A periostitis of a very acute form, almost

invariably suppurating, and accompanied by necrosis, is very common in the fingers, where it chiefly affects the unequal phalanges. The pain is very great, but may be relieved by an early and free incision down to the bone, which, nevertheless, does not usually avert either suppuration or necrosis.

(b) *Chronic periostitis* is usually due to some diathetic cause, but may result from injury, or from some continuous pressure. It is most frequent on the superficial parts of the skeleton, as the tibia, clavicle, skull, and ribs, but may affect any bone; and it is often observed at the origin or insertion of muscles. When the disease arises from a general cause, such as syphilis, many parts of the skeleton are affected; when from a local cause, usually only one.

SYMPTOMS.—Chronic periostitis generally takes the form of what is called a *node*—a tender, more or less painful, rounded or oval swelling; at first tense and hard, afterwards softer, or even fluctuating. The pain is much greater at the outset, from the tension of the parts involved, and is generally worse at night. Subsequently the swelling becomes indolent, and painless, unless pressed upon. Nodes are due to a localised inflammation. The cambium-layer of the periosteum and its external layer proliferate and become filled with leucocytes, thus forming a well-marked projection on the bone, which may undergo resolution, suppurate, or ossify, according to circumstances.

PROGNOSIS.—In chronic periostitis this is usually favourable. Under the influence of early and suitable treatment, the inflammatory products are completely absorbed, and the bone resumes its natural shape. If the chronic inflammation of the periosteum be permitted to proceed unchecked, a deposit of new osseous lamellæ usually takes place on the surface of the affected bone, giving rise to permanent thickenings, or even to osteophytic growths. These are composed of light porous bone, with a rough surface. The skeleton of a syphilitic subject will often present numerous thickenings of this nature. On making a section of the bone, it is easy to see that the new bone is superimposed upon the old, and is formed by the periosteum.

TREATMENT.—When due to a local cause, the swelling will often spontaneously subside with rest to the part, but in obstinate cases iodide of potassium internally, and iodine ointment or blistering externally, may be required. If the subject be unhealthy, or if the original injury be considerable, suppuration may take place, when the treatment will be that of an *inflammatory abscess*. *Syphilitic nodes*, which are a very common expression of chronic periostitis, yield rapidly to the influence of iodide of potassium, which in some cases may usefully be combined with a mercurial course. Blistering or friction externally is hurtful in such cases. Syphilitic nodes are not at first prone to suppuration, and even when they become soft and fluctuating, and the skin reddens over them, they should not be mistaken for abscesses, as they readily become absorbed under suitable treatment.

(c) *Periostitis after typhoid fever.*—A peculiar form of chronic periostitis is occasionally observed as a sequel to typhoid fever. It occurs during

convalescence, and without general symptoms. It takes the form of hot, painful, and tender nodes, frequently symmetrical, and often placed on the tibia; the disease is also found on the ribs and other bones. It may be associated with necrosis, but if so the extent of the dead bone is small in proportion to the inflamed area of periosteum. The general health is not seriously affected, and the disease is very amenable to treatment by iodide of potassium, combined with iodide of iron.

B. Osteitis is an inflammation chiefly affecting the bone-substance; this form may also be *acute* or *chronic*.

(a) *Acute osteitis* is neither clinically nor pathologically to be distinguished from acute osteomyelitis or endostitis (*see Osteomyelitis* s).

(b) *Chronic osteitis* is a disease beginning in the bone, in which the chief changes from first to last occur, the periosteum being secondarily engaged. This affection may result from injury, or be excited by exposure to cold; but it often depends on constitutional predisposition, such as the syphilitic, the strumous, the gouty, or the rheumatic diathesis, the first being the most frequent cause. It may occur in any part of the skeleton; the chief changes, when produced by syphilis, occur in the shafts of the long bones. They consist mainly of hypertrophy, and the bone is ultimately increased in thickness, in length, and generally in density: its interior is often transformed into dense bone-tissue, and the medullary cavity is obliterated. Another form, associated with the strumous diathesis, is generally seated in the joint-ends of the long bones and in the spongy bones. It is prone to end in suppuration, accompanied by either caries or necrosis. The gouty and rheumatic forms are associated with evidence of the presence of either of these diatheses.

PATHOLOGY.—Increased vascularity first takes place, the Haversian canals enlarge, the canaliculi disappear, the cancelli enlarge to contain the inflammation-products, and the earthy matter diminishes; hence the inflamed bone softens, and, if ulcerated at this stage, will be found comparatively light and porous. When the inflammation affects the superficial laminae of the bone, the periosteum becomes thick and vascular; if the deeper parts are involved, similar changes will occur in the endosteum. The porous condition of the bone may become permanent, when the condition is called *osteoporosis*, the result of so-called rarefying outitis; or the granulations become transformed into new bone, and the cancellated structure is filled with osseous deposit, so that the whole of the inflamed area becomes very dense, and is then said to be sclerosed; or the inflammation-process may terminate in suppuration, followed by caries, necrosis, or an abscess of the bone, which last may be either diffused or circumscribed.

SYMPTOMS.—These are insidious, very obscure at the outset, and may be mistaken for those of chronic rheumatism, or mere periostitis. They consist chiefly in aching, growing pain in the affected bone, with characteristic remissions and nocturnal exacerbations. The bone is tender on pressure, and feels increased in bulk at first, from the infiltration of the immediately sur-

rounding soft tissues; subsequently the bone itself enlarges. There is often increase of heat in the limb. The progress is very chronic, and if unchecked by treatment may give rise to considerable deformity.

TREATMENT.—This should be directed to the cause of the disease. If this be syphilis, an antisyphilitic treatment will be followed by good results; even in chronic bone-inflammation, not dependent on syphilis, iodide of potassium is often of great service. Local counter-irritation may also be employed. Often the cause cannot be made out, and if iodide of potassium fail in producing an effect, we must fall back on general treatment. In the early subacute stage, rest, with elevation of the affected part, is very desirable. Warm fomentations, followed by iced compresses, relieve the suffering. If there be much pain and tension, leeches should be applied. Puncturing the tissues down to the inflamed bone with a tenotomy knife or fine bistoury, relieves the tense periosteum, and allows extravasation beneath it to escape, so that the pain is promptly abated.

(c) *Osteitis deformans*.—A peculiar form of chronic inflammation of bone has been described by Sir James Paget under this title, from the changes it produces, both in the form and density of the affected bones. It is a chronic osteitis of the most extreme type. It begins in middle age, and may continue for an indefinite time without influence upon the general health, which distinguishes it clinically from other bone-inflammations. It is usually symmetrical, and affects chiefly the long bones of the lower extremity and the skull. At first the bones enlarge and soften, from excessive production of imperfectly developed structure and increased blood-supply, and, yielding to the weight of the body, become curved and misshapen, but the limbs, although deformed, remain strong and fitted to support the body. In its early period, and sometimes throughout its course, the disease is attended with pains in the affected bones, which vary widely in severity, and are not especially nocturnal or periodic. It is not attended by fever, nor associated with any constitutional disease. It differs from the chronic osteitis dependent on simple inflammation of bone or that produced by gut or syphilis, in affecting the whole length of the bone. Hyperostosis and osteoporosis dependent on these latter causes rarely affect the entire bone. No treatment appears to produce any effect upon this disease.

C. Osteomyelitis is an inflammation chiefly affecting the interior structure of the bone. Like the former, it may be *acute* or *chronic*.

(a) *Acute osteomyelitis* or *endostitis* is a suppurative inflammation of the medulla and bone, which very frequently ends in septic poisoning and necrosis. It is nearly always associated with bone-injury, and most frequently happens after amputation, or gunshot fractures, in which the cancellated structure is injured, a severe contusion of the bone, an injury to the periosteum, or exposure to sudden extremes of heat and cold is capable, under some circumstances, of producing the disease.

SYMPTOMS.—The symptoms are obscure, more especially if there be no opportunity of examining

the affected bone, as the changes in the bone are often masked by inflammation of the superficial parts. They usually make their appearance from five to ten days after the injury to the bone. The pain may not be excessive; there is fever and perhaps rigor. If there be a wound the secretion from it diminishes in quantity, and becomes less healthy; the medulla protrudes from its central cavity; the parts soon become surrounded by putrescent fluid; and the symptoms become those of more or less intense septicæmia. The periosteum sometimes, but not always, separates from the bone. In young persons the disease is sometimes arrested at the epiphysis; but in the adult the whole length of the bone is liable to be affected. The risk of septic poisoning is infinitely greater in osteomyelitis than in osteo-periostitis. Thrombosis of the bone-veins is especially prone to happen, and by the breaking down of the clot septic emboli are carried into the circulation, and deposited in the liver, lungs, and elsewhere. It is in this disease, too, that fatty embolism takes place—a condition associated with a very acute and fatal form of blood-poisoning. The prognosis is generally bad. It is impossible to distinguish acute osteomyelitis from acute osteo-periostitis, arising from non-traumatic causes. In military hospitals, in war time, acute osteo-mylitis is often epidemic.

TREATMENT.—Where the symptoms lead us to suspect osteomyelitis, although the medullary cavity of the bone may not have been exposed, it may be desirable to trephine the bone, and if suppuration in its interior be discovered, it will be necessary to amputate, and as soon as the nature of the disease is recognised, this affords the best chance of saving the patient's life. The chief difficulty consists in arriving at a correct diagnosis and deciding when it becomes necessary to interfere. This may best be done by observing the general progress of the case, and locally by the introduction of a probe into the medullary cavity when this is exposed. If it reach healthy bleeding medulla near the surface, we may temporise, if the constitutional symptoms admit of this; but it is rare for the disease once commenced to be limited—it has an extreme tendency to become diffused. Experience shows that nothing short of amputation at, or even above, the next joint is sufficient to arrest the consequences of the malady, and this must be done before the systemic poisoning has become marked. Amputation in the continuity of the affected bone is worse than useless.

(b) *Chronic osteomyelitis* is an obscure affection, not to be distinguished, either clinically or pathologically, from chronic osteitis. It may terminate in sclerosis, or in the formation of an abscess. See Chronic Osteitis.

2. **Abscess.**—This is a term applied usually to a limited suppuration in the bone, unattended by necrosis. Young adults are most prone to the disease, or boys about the age of puberty; it is very rare in women. It is the result of a chronic inflammation of bone, which may be associated with some injury. This affection is most frequently met with in the upper or lower extremities of the tibia, just external to the epiphyseal cartilage, less frequently in the ends of

the femur, only occasionally in other bones, and very seldom in the compact tissue anywhere.

SYMPTOMS.—A circumscribed, slightly elevated, very tender and painful swelling may be discovered. This is due to a local periostitis with new bone-deposit, and the bone itself is often half an inch or an inch longer than its fellow, by reason of increased activity of growth at the epiphysis. The skin and superficial parts are unchanged at first, or there may be but trifling subcutaneous oedema. There is often slight local increase of temperature. The pain, on deep pressure at the central point, is often intolerable. It is intermittent at first, but generally worse at night. After a time it becomes continuous, and deprives the patient of all rest, owing to its severity. The abscess may persist with little change for months or years. The symptoms generally resemble those of osteitis, from which at the outset it is difficult to distinguish this affection. When the abscess tends to reach the periosteal surface, the soft parts become engaged, and there will be slight redness and oedema of the skin. Rarely the pus makes its way into the adjacent articulation, in which it sets up destructive inflammation; but usually the joints are free from implication. The subjects of the disorder have often suffered from antecedent bone-disease. Evidence of this should be looked for, as giving a clue to the diagnosis.

TREATMENT.—Spontaneous cure cannot occur—even if the abscess discharge itself, a permanent fistula will usually remain. It is necessary freely to lay open the abscess-cavity. A crucial incision must be made through the soft parts, down to the bone, at the most tender and prominent point, and a disc of bone removed by the bone-trephine—an instrument without a shoulder, about half-an-inch in diameter. The sudden loss of resistance indicates the piercing of the abscess-cavity. The layer of granulation-tissue lining its interior should not be interfered with, but the cavity simply washed out. The pus is often foul, and greenish in colour. The wound should be dressed antiseptically; granulations presently fill it, which are subsequently transformed into a fibrous cicatrix. Immediate and permanent relief follows the operation. If the abscess is missed, the trephine may be re-applied, or drill punctures made in the most likely directions in the adjacent bone, in order to discover the pus. Sometimes an error of diagnosis is committed, and the symptoms are found to arise from chronic osteitis, without suppuration. The operation, however, affords relief in these cases also. Where there is doubt, a preliminary course of iodide of potassium will often resolve it.

3. **Caries** is a form of chronic inflammation of bone, which has been likened to the process of ulceration in the soft tissues. It is generally found in the spongy bones, in any part of the skeleton, the vertebrae and tarsus being the parts most commonly affected. There are two forms of the disease—one, *simple caries*, resembles an indolent ulcer of the soft parts, is most common in the flat or short bones, but is sometimes met with in the compact tissue of long bones; the other, *fungating caries*, is often met with in the articular ends of the long bones, and usually

organs, and hence the symptoms in cases of hæmorrhage into the middle lobe are to be ascribed to irritation of this region. This fact also explains the absence of the symptoms when the hæmorrhage occurs into the lateral lobes. There is absolutely no evidence or the slightest value in support of Gall's hypothesis. The facts of clinical medicine go a considerable way in diametrical opposition to it, if they are not themselves sufficient entirely to overthrow it.

Cerebellar Peduncles.—Respecting the effects of disease of the ratiiform tracts or inferior cerebellar peduncles we have no definite knowledge.

Cases, however, are on record in which lesions have been found involving principally either the superior or middle cerebellar peduncles. The symptoms, in the main, agree with those observed by Magendie on section of the middle peduncle in the lower animals. The chief effect of this lesion was to cause an irresistible tendency to roll over towards the side of lesion. Together with this rotatory disturbance of the equilibrium, a peculiar distortion of the optic axes was observed, the eye on the side of lesion being directed downwards and inwards, the other looking upwards and outwards.

In a case described by Curschmann (*Deutsche Archiv f. Klin. Med.* xii. 356), along with appearances of basilar meningitis, which somewhat complicates the case, there was found a focus of softening, surrounded by capillary hæmorrhages in the right superior cerebellar peduncle. The symptoms observed in this case were a rotatory distortion to the right side, to which position the patient invariably returned when resistance to this movement was withdrawn. There was no motor paralysis, nor was there any distortion of the optic axes.

A case has been put on record by Nonat (*Comptes Rendus*, 181) of apoplectic extravasation into the right middle peduncle of the cerebellum and right cerebellar hemisphere. In this case the head and trunk were twisted towards the right side, and the ocular symptoms were also present, the eyes being immovable in a position of skew deviation. Other cases are on record in which the cerebellar peduncles have been involved in more extensive lesions, but the symptoms, though not opposed to those above related, are incapable of differential analysis. The special diagnostic symptoms, therefore, of lesion of the cerebellar peduncles are what are frequently termed 'forced movements' (*Zwangsbewegungen*), or distortions of the normal axis of the trunk. The exact direction of the distortion, in consequence of lesion specially limited to one or other peduncle on the right or left side respectively, is somewhat doubtful, though as a rule it has been found towards the side of lesion. Much, however, will depend on whether the lesion is of an irritative or inflammatory, or of a destructive character. A lesion of an irritative nature, though occupying the same position as a destructive lesion, would exactly reverse the direction of the distortion of the head and trunk. D. FÉRÉRIER.

CEREBRITIS.—Inflammation of the brain-substance. See BRAIN, Inflammation of.

CEREBRO-SPINAL FEVER.—SYNON: Epidemic Cerebro-spinal Meningitis, The Black Sickness (popular, Dublin); *Fe. Méningite cérébro-spinale épidémique*; Ger. *Cerebral-typhus*; *Epidemische-meningitis*.

DEFINITION.—An acute epidemic febrile disease, characterised by sudden invasion, with extreme nervous shock, vomiting, excessive pain referred to the back of the neck and spine, spasmodic contraction of muscles, excessive sensibility of the skin, and frequently delirium; accompanied by purpuric eruptions, either circumscribed, raised, hard, and shotty to the feel, or extensive purpuric spots or patches, frequently accompanied by vesicular eruptions usually of herpetic but sometimes of a pemphigoid character, and frequently purulent inflammation of the eyes. *Post mortem* there are found: inflammation of the membranes of the brain and spinal cord, especially of the arachnoid, with deposit of white, yellow or greenish-yellow lymph upon the surface of the arachnoid, especially at the base of the brain and anterior portion of the medulla oblongata and spinal cord, and effusion of serum into the ventricles and sub-arachnoid spaces.

ÆTIOLOGY.—*Age*—The disease usually attacks those approaching the age of puberty or in early adult life, it is seldom met with after thirty-five years, and is very rare after the age of forty. It is not unfrequent in young children.

Sex.—It is much more frequent in males than females, robust males between the ages of fifteen and thirty are its favourite victims.

Occupation.—It seems specially to attack young recruits in the army, as was the case in the French epidemics. In Dublin it was specially severe among the recruits of the Royal Irish Constabulary stationed in the police barracks in the Phoenix Park. There does not seem to be any other occupation which predisposes to the disease. Excessive fatigue seems to predispose to the disease, it has arisen after a hard day's hunting, foot-racing, long walks, dancing, or in children exhausted from out-door play.

Season and Climate.—It is widely distributed in the temperate zone. It prevails more in cold than in hot weather, in Ireland it has usually prevailed in winter and early spring.

General Sanitary Conditions.—It seems to be less influenced than any other epidemic affection by general sanitary conditions.

Communicability.—It is generally believed not to be contagious, a few doubtful cases of contagion have been recorded; except, however, in cases where it has appeared as an epidemic among recruits, there are few instances of more than one case arising in any particular house or circumscribed locality.

Epidemic Influence.—The disease is undoubtedly epidemic.

Translucent Fluid.—It has been suggested that the disease owes its origin to the use of breadstuffs made from diseased grain.

ANATOMICAL CHARACTER.—Cadaveric rigidity is well marked; large purpuric patches form after death even in cases where there were no purpuric symptoms during life; in some cases the whole body has turned black. On incision a large quantity of dark, tarry-looking blood exudes; the muscles are darker than usual, and in prolonged cases much weakened and wasted. There is increased vascularity of the scalp; the cerebral sinuses are much distended with dark blood; serum is found in the sub-arachnoid spaces and ventricles, all the membranes of the brain may be more or less congested, the arachnoid being always extremely vascular and opaque from deposits of lymph—the opacity varies from slight milkiness to thick and dense deposits. The most marked intracranial lesion is the white-yellowish or yellowish-green 'fibrino-purulent' deposit found at the base of the brain. This deposit varies somewhat with the duration of the disease in cases which die early the deposit is usually slight, whitish, and soft; in those which live for a week or so the deposit is yellowish or greenish, in prolonged cases the deposit is more white and pure, the effused serum greater in quantity, and the vascular fulness less. The origins of the nerves seem to be buried in and compressed by the deposit. The brain-substance itself is more vascular than normal, but not otherwise altered. In the spinal cord the lesions are similar to those found in the brain and its membranes. In some cases purulent infiltration of the eyeball and effusion into the joints have been met with. The lungs, liver, and spleen have been found much congested in many cases.

SYMPTOMS.—The patient is usually attacked suddenly when in apparently vigorous health by faintness, vomiting of greenish matter, and intense pain referred especially to the back of the head and neck; the extremities become cold, the patient becomes insensible and sometimes convulsed; the limbs become rigid. On recovering from the collapse, the patient complains of great pain in the head, back of neck, and along the spine; the head is drawn back, so as to be almost at a right angle with the spine; the whole back is sometimes arched, as in tetanus, the muscles become rigid, and the skin excessively sensitive; neuralgic pains are also complained of in all parts of the body. In most of the severe cases eruptions appear within the first twenty-four hours, the eruption usually appears first on the legs, and is frequently confined to the lower extremities; the spots are usually black, raised, about a line in breadth, and feel like a grain of shot under the skin, sometimes these raised spots are surrounded by a dark purplish areola, in most cases large purpuric patches of many inches in extent form on various parts and, sometimes coalescing, cover the entire body. Vesicular eruptions are also common; these usually have the character of herpes zoster, and are most frequent on the face, neck, and shoulders. The herpetic eruptions are met with as frequently in mild as in severe cases. Pemphigus sometimes appears in the advanced stages of the disease. When reaction sets in, the tem-

perature is found to have risen to from 100° to 103° or 104° Fahr. In many cases the temperature never rises, and the patient dies in the collapse; the respiration becomes of a sighing character; the pulse rises to about 120, and has a peculiar jerking character, giving a sharp up-stroke to a sphygmographic tracing. The foregoing symptoms are very variable; any one, or even a considerable number of them, may be absent throughout the whole course of the case.

COMPLICATIONS AND SEQUELÆ.—Complications connected with the nervous system are the most common; paralysis of one or more limbs is common, of a homiplegic character, and most frequently attacking the arm; deafness is not very common, but has been met with in several cases, and sometimes becomes permanent. The eye-complications are among the most frequent and most serious. The eye is frequently attacked with a low form of inflammation, terminating in purulent infiltration of the whole or part of the organ; the cornea is more frequently attacked than any other portion; and this sometimes giving way, the whole contents of the globe escape, causing permanent loss of sight. The sight is also often permanently impaired by iritis, or opacity of the cornea. In many cases, however, the inflammation completely subsides. It is remarkable that it is the right eye which is usually attacked, seldom that both eyes are affected, and scarcely ever the left eye alone. Acute inflammation of the larger joints is a frequent complication in some epidemics; this often terminates in purulent effusion into the joints. Hemorrhages are frequent in the more malignant forms, and are almost always present in cases where the purpuric blotches are of large extent, these hemorrhages have occurred from the nose, uterus, bowels, kidneys, and ears in about the foregoing order of frequency. Gangrene is occasionally met with, and the cases in which it occurs are usually fatal. In some cases toes have been lost and the patient recovered, the purpuric patches have also sloughed without serious danger to the patient's life.

DIAGNOSIS.—The disease is liable to be confounded with typhus fever on account of the petechial rash, but is distinguished from typhus by the rash appearing suddenly without any previous mottling of the skin. The nervous symptoms also distinguish it from typhus, although in a case of typhus complicated with cerebro-spinal meningitis the diagnosis is extremely difficult, and may be impossible. It is distinguished from *purpura hemorrhagica* by the intensity of the fever and the localised nervous symptoms. The malignant cases are more likely to be mistaken for malignant scarlatina than for any other disease, and must be distinguished therefrom by the rash, sore throat, and nervous affections. In some cases it has been indistinguishable from malignant scarlatina, especially where death occurred within twenty-four hours, and both diseases were epidemic at the time.

PROGNOSIS, DURATION, TERMINATION, AND MORTALITY.—The prognosis, duration, etc., of the disease depend much upon the form the affection assumes, and for convenience we may divide the disease into the following forms:—

1st. Cases of a very mild form, terminating in recovery; the duration being usually from one to three weeks.

2nd. Cases of a very severe form, setting in suddenly; the symptoms being very violent and well marked, accompanied by purpuric spots and blotches, with a tendency to hæmorrhages, with deep collapse and coma; usually terminating fatally in from a few hours to three days.

3rd. Cases of medium severity, where all the nervous symptoms set in with less suddenness than in the second class of cases, purpuric blotches not being usually present, and no hæmorrhages. These usually yield to treatment, and terminate in recovery in from two to six weeks.

4th. Cases which set-in either in a mild or in a severe form, but in which on the subsidence of the fever the strength does not return, convalescence is retarded or ceases altogether, and the patient falls into a general atrophic condition, and usually dies in from three to six months of marasmus.

By deciding to which of the above classes the case belongs, the prognosis will be to a great extent determined. The chief indication of danger is the early appearance of purpuric and hæmorrhagic conditions.

The mortality in cerebro-spinal fever is very high—probably on an average about 60 per cent. In some of the American epidemics it is placed as high as 75 per cent. Among the Irish constabulary it reached 80 per cent. Like other epidemic diseases the mortality is highest at the commencement of the epidemic. It is most fatal about the age of twenty, and less so under fifteen years.

TREATMENT.—The treatment in the early stage must be directed to recovering the patient from the collapse. This is best done by the application of heat, the administration of small quantities of stimulants or stimulating enemata and the application of sinapisms over chest and back. In the next stage of the disease attention must be almost altogether directed to allaying the spinal irritation, and promoting the absorption of the effused matters. The extreme irritation will be best diminished by the use of belladonna and bromide of potassium. The pain, which is extreme, will yield best to frequent and considerable doses of opium; indeed many physicians rely altogether on opium as the curative agent. With a view of promoting absorption of the effused matters, mercury and iodide of potassium have been chiefly relied upon. In the more sthenic cases calomel may be employed with benefit in small and repeated doses. The disease being usually of an æsthenic type, mercury will seldom be well borne, and iodide of potassium should be preferred. Leeches applied to the back of the neck, behind the ears, or to the temples, produce great relief of the excessive pain in the head and upper part of the spine. The application of ice to the head and spine temporarily allays pain, but there is little evidence of permanent benefit being derived therefrom. In prolonged cases blisters applied along the spine have been favourably spoken of. The local complications must be treated as they arise, and according to general principles applicable in such case.

Stimulants are required in considerable quantity;—a very large number of the cases which present adynamic symptoms

T. W. GRIMSHAW.

CHALAZION (χλαζα, hail)—A small encysted tumour of the eyelids, colourless and transparent, and resembling a hailstone.

CHALK-STONES.—This name is applied to the deposits which are formed in connexion with the gouty diathesis, especially in the joints. They are thus denominated from their appearance and physical characters, in which they more or less resemble chalk, but in their chemical composition they are entirely different, consisting mainly of urate of soda. See GOUT.

CHALYBEATE WATERS (*chalybs*, steel).—Mineral waters which contain iron. See MINERAL WATERS.

CHANCER (Fr. *chancre*).—Hard chancre is the initial manifestation of syphilis. See SYPHILIS. Soft chancre, see VENEREAL DISEASE.

CHANGE OF LIFE—SYNON.: Climacteric epoch; Sexual involution; Fr. *Ménopause*. Ger. *Menstruationsende*.

DEFINITION.—The time of life in a woman when the functions of the uterus and ovaries cease, menstruation terminating,—a period when disease of these organs is especially prone to occur, and when various constitutional disturbances are almost certain to arise.

ANATOMICAL CHARACTERS.—Great changes occur in the sexual organs—the ovaries lose their smooth outline, and after a while become shrivelled up, occasionally only a trace of them remaining; the Fallopian tubes diminish in size, and sometimes become obliterated; the walls of the uterus atrophy, its cavity becomes much smaller, and the cervix disappears altogether.

SYMPTOMS.—The term 'change of life' is used among women very widely to signify everything which affects them at this critical time. It is so rare for the transition from activity to inactivity to take place without some disturbance locally, or constitutionally, that women are apt to neglect seeking advice for symptoms which should demand careful treatment, believing as they do that it is natural to suffer in such ways at 'the change.' There is no fixed period for the climacteric epoch, though roughly it may be said to occur between the ages of forty-five and fifty. Certain causes are apt to determine the time—amongst these are parturition and lactation, febrile attacks, such as typhus or acute rheumatism, profuse hæmorrhages, fright, &c.

The symptoms vary much. In some women the change is abrupt, menstruation ceasing all at once after perfect regularity; in others, and more frequently, the change is prolonged, the catamenia being irregular for many months, and varying as to periodicity and quantity. Frequently, after a long interval, a profuse flow with clots occurs, and this is very often attributed to a miscarriage. This loss is frequently beneficial, and if it do not take place, or relief be derived from vicarious discharges, such as bleedings from hæmorrhoids, the excess of blood gives rise to headaches, flushes, vertigo, and a host of other unpleasant symptoms. The

balance between the nervous and circulatory systems is upset; irritability of temper, hyper-sensitiveness and all sorts of fancies arise, or depression sometimes amounting to melancholia ensues. If germs of disease exist, the uterus is especially prone at such time to develop them, so that carcinoma, fibroid disease, and polypus frequently present their first symptoms at this epoch. The importance, therefore, of an early examination cannot be too forcibly dwelt on, or the mischief of delay from considering the abnormal condition as typical of 'the change of life,' as a natural consequence, which will therefore right itself. At these times pruritus of the vulva, vascular growths at the orifice of the urethra, and cutaneous eruptions are especially likely to occur. There is a tendency to grow fat, and become coarse, frequently hairs appear on the face. The breasts often become very large and pendulous, and this with the increase in the size of the abdomen from flatus, and the deposition of fat in its walls, together with the cessation of menstruation, not infrequently gives rise to the supposition of pregnancy. To this imaginary state the term *Pseudocyesis* has been applied, and it is often almost impossible to set aside the opinion of the woman regarding her supposed condition. The headaches, neuralgia, loss of memory and nervous symptoms appear to be due to disturbance in the ganglionic system of nerves, with which the uterus and ovaries are largely supplied. If insanity arise the most common form it assumes is hypochondriasis or melancholia.

TREATMENT.—This must be directed to regulating the secretions. Generally constipation, previously troublesome, becomes aggravated; and portal congestion frequently occurs. Saline purgatives are especially beneficial, and these may be judiciously administered in the form of mineral waters, such as the Hunyadi János, or Friedrichshall. Blue pill with aloes is often very useful. The headaches and reflex nervous symptoms may be best combated by the administration of bromide of potassium, and this drug appears to act as a direct sedative to the sexual organs, besides diminishing the amount of blood determined to them. Occasionally, bleeding from the arm or cupping gives great relief. Attention must above all be paid to the diet. It should be plain and unstimulating; beer and spirits should be prohibited, and only light wines, if any, allowed. Tepid baths are useful. Late hours, heated rooms, and excitement of all kinds should be avoided. If local troubles arise, they must be treated according to their indications; as a rule, abstracting blood from the uterus does harm, but leeches to the anus are sometimes beneficial. It is clearly impossible to map out any empirical line of treatment for a condition in which the symptoms are so variable.

CLERMONT GODSON.

CHAPPED NIPPLES. See BREAST, Diseases of; and NIPPLE, Diseases of.

CHAPS.—**SYNON.** : Rhagades.—Cracks or fissures of the skin occur where the integument has become hardened by infiltration, as in the erythema of the hands and wrists of cold weather, in chronic eczema, psoriasis and lepra vulgaris. The treatment for chaps consists in

protection from the atmosphere; careful drying after the hands have been washed or wetted; and the use of zinc ointment and glycerine soap. Diluted glycerine, vaseline, and cold cream are also popular remedies. ERASMUS WILSON.

CHELOID (χελή, a claw).—**SYNON.** : Cheloides, Cheloma; Fr. *Dartre de la graisse*; Ger. *Keloid*.

DEFINITION.—A tumour of the skin resulting from over-growth of connective tissue within the corium.

ÆTIOLOGY.—Cheloma may be idiopathic or accidental, and in both cases it is referable to a diathesis. When of accidental origin it is commonly associated with a cicatrix, and is then developed in the midst of the cicatrix-tissue. This form of the tumour has been denominated *cheloides spuria* or *traumatica*, and, as such, has been seen scattered numerously over the chest and shoulders as a sequel of acne.

The cause of cheloma must be sought for in that vital source from which is derived aberration of nutrition in general. It is a consequence of feeble controlling power, and may be resident in the skin alone, or be dependent on a want of vigour of the constitution of the individual.

The traumatic cheloid may follow a light as well as a severe injury of the skin, such as a boil, a blister, a leech-bite, or even the irritation of a stimulating liniment; it is sometimes met with in the scars of strumous abscesses or ulcers, but is most common in the cicatrices of burns or scalds.

ANATOMICAL CHARACTERS.—At its first development cheloma occupies the fibrous portion of the corium. As it increases in bulk it pushes the vascular layer outwards and stretches the corpus papillare, obliterating the capillary network, more or less completely. In its aggregate form when it presents itself as a flat plate, raised for a quarter of an inch above the level of the adjoining skin and sinking to a similar extent into the corium, it has the appearance of being tied down by strong cords or roots at either end, and frequently overlaps the healthy skin along its borders. In this state it is seen to be composed of strong fibrous bands closely interlaced with each other and enveloped by a smooth transparent pinkish layer, in which may be detected a scanty vascular plexus converging to venules which sink between the meshes of the fibrous structure.

Around the circumference of one of these larger flattened tumours, such as is commonly met with on the sternum, and measuring several inches in diameter, there will generally be observed a few scattered knots. These are developed in the fibrous sheath of the arteries at a short distance from the mass, and, being thus linked to the central growth, are subsequently drawn into the focus of the tumour. And the development of the so-called roots is explained, by the propagation of the proliferating process by the coats and sheaths of the blood-vessels communicating with the central tumour.

DESCRIPTION.—Cheloid has received its name from its habit of throwing out spurs from its circumference, these spurs having been compared to crab's claws. It originates in a gradual

oval, or oblong tubercle or knot in the skin, and this may be followed by a second in its immediate neighbourhood, or sometimes by a cluster of three or four. When two of these knots are situated at a short distance apart they are apt to become connected by a cord of the same structure as themselves, and to give rise to what has been called a *cylindrical, club shaped, or dumb-bell* cheloid. When three or four knots are grouped near together they are disposed to become blended by growth and produce an oval or square-shaped cheloid, and when the growth extends from these latter into the surrounding integument the appearance denominated *radiciformis* is established. Cheloma being due to a tendency to overgrowth or hyperplasia of connective tissue within the skin, it may appear on several parts of the integument at the same time, one of the most common seats of its development being the sternum, which it generally crosses transversely. It is often solitary; is more commonly composed of five or six tumours, discrete or confluent; but has been met with occasionally to the number of fifty or sixty tubercles or more.

COURSE AND PROGNOSIS.—Cheloid rarely gives rise to much inconvenience or attains any considerable magnitude, and when left to itself progresses very slowly or remains stationary for a number of years or for life, and we have known it to disappear spontaneously. Its subjective symptoms are of no great severity, being limited to itching, tingling, and smarting, and more or less uneasiness in moving the limbs, or from pressure when sitting or lying in bed. It has no tendency to desquamation or ulceration.

TREATMENT—Being dependent on a diathesis, surgical manipulation has generally proved unavailing in cheloma. It might be expected to recur in the cicatrix of a wound made for its removal, or in the scars of a suture employed to hold the cut edges together, and such has proved to be the case. The most successful treatment consists in covering up the tumour with a mercurial or iodine plaster, or even with simple emplastrum plumbi. The writer's favourite treatment is to paint it with a spirituous solution of soap and iodide of potassium, and then cover it with an adhesive plaster spread on washleather, repeating the application as often as the plaster becomes loosened. We have seen a multiple cheloma cured in this way; aided by mild doses of the perchloride of mercury. The combination of warmth and moisture, such as is produced by a plaster, is an important element in the cure. But irritants, caustics, and the knife are all equally objectionable and valueless.

ERASMUS WILSON.

CHELTENHAM, in Gloucestershire. Common salt waters. See MINERAL WATERS.

CHEMOSIS (*χημη*, a hole).—A swollen condition of the conjunctiva, caused by effusion into its tissues around the cornea, which thus appears as if placed in a hole or hollow. See EYE and its Appendages, Diseases of.

CHEST, Diseases of the.—Following the plan adopted in the general article on the Abdo-

men, it is proposed in the first place to give an outline of the diseases of the chest, and then to indicate the principal points bearing on their clinical investigation.

GENERAL SUMMARY.—The diseases of the thorax and its contents may be conveniently divided into certain groups, namely:—

I. Diseases of the chest-walls, or extending inwards from these walls.

II. Diseases of the respiratory apparatus contained within the thorax, namely:—1. Pleurae. 2. Trachea. 3. Main Bronchi. 4. Lungs.

III. Diseases connected with the circulatory system, including:—1. Pericardium. 2. Heart. 3. Great vessels within the chest, both arteries and veins.

IV. Diseases originating in the mediastinal cellular tissue.

V. Diseases of the absorbent vessels or glands within the chest; of the thoracic duct; and of the thymus gland or its remains.

VI. Diseases of the oesophagus.

VII. Diseases of either of the important nerves traversing the chest.

VIII. Diseases of the diaphragm.

IX. Diseases encroaching upon the chest from the abdomen or from the neck.

The particular diseases comprehended within most of the groups just enumerated are very numerous, and they will be described under their respective articles. Affections connected with the chest constitute a large proportion of the cases which come under observation in practice. This will be readily understood when we remember that the thorax encloses organs essential to life, which are never at rest, and which are constantly more or less exposed to influences liable to injure them. They may be mere *functional disorders*, and to these the heart is especially prone; but serious *organic diseases* are also exceedingly common, and rank very high as causes of death. Moreover, they may either come under the category of *local* affections, though even then they frequently depend upon some cause acting through the *general system*, such as exposure to cold or wet, or they arise in the course of some *general* malady. For instance, pulmonary complications are of common occurrence in connexion with fevers and various other diseases; the heart is implicated in a large proportion of cases of rheumatic fever, and malignant disease is not infrequently manifested by a local development of cancer in connexion with certain of the thoracic contents. The structures within the chest have an important mutual influence upon each other, and they may also be affected, either directly or indirectly, by local diseases involving other parts of the body, such as the abdomen or the central nervous system.

CLINICAL INVESTIGATION.—It may be confidently affirmed, that the means which we now possess for investigating diseases connected with the chest are so adequate and precise, that any one possessing the requisite knowledge and skill, and who carries out the clinical examination properly, can, in the very large majority of cases, arrive at a diagnosis with certainty and accuracy. At the same time it must be remembered that every complaint referred to this region, however trivial it may appear to be, does require system-

atic and thorough investigation, otherwise very serious mistakes are constantly liable to be made. Of course, cases also do come under observation occasionally which are obscure, and which may call for repeated examination before a correct diagnosis can be formed; and exceptional instances occur in which no satisfactory conclusion can be arrived at. The previous general history of the patient, the hereditary history, and the account of the origin and progress of the illness, often afford signal aid in the investigation of chest-affections, and ought never to be overlooked. The symptoms to which these affections give rise are necessarily various. Pain or other morbid sensations are very commonly complained of, but only in a comparatively few instances are these at all significant, and they can never be positively relied upon in making a diagnosis, while they are often absent in diseases of the most serious character. The important organs, namely, the lungs and heart, usually present more or less disturbance of their functions when they are affected, but grave diseases may exist without any such disturbance. The different structures within the chest have a mutual influence upon each other, and thus other symptoms besides those connected with the structure actually diseased may be apparent. For instance, the lungs and heart are thus very intimately associated; while aneurisms or growths often disturb these organs seriously, or interfere with the air-tubes, nerves, veins, and other structures. In consequence of more or less interference with the circulation, various symptoms in parts remote from the chest are frequently originated; and distant organs may become the seat of organic lesions as the result of long-continued mechanical congestion, a new train of symptoms being thus set up. The general system may be in this manner affected, whilst pyrexia, wasting, and other general symptoms are often associated with chest-diseases. Lastly, morbid conditions within the thorax may directly affect the abdominal organs; or may make their way through the diaphragm into the abdominal cavity.

Physical Examination constitutes an essential and most important part of the clinical investigation of the chest and its contents. Indeed, without this examination no certain and exact diagnosis can ever be made. This subject is fully discussed in other appropriate articles, and here it need only be mentioned that the methods of examination which are usually required, and which should in every case be practised, are:—1. *Inspection*. 2. *Palpation*. 3. *Percussion*. 4. *Auscultation*. Other modes which may be called for include—5. *Measurement* (not uncommonly). 6. *Succession*. 7. The use of *special instruments*, directed to the investigation of particular organs, such as the spirometer, cardiograph, sphygmograph, aspirateur, cesophageal bougie, &c. See **PHYSICAL EXAMINATION**, and **DISEASES OF THE SEVERAL ORGANS**. **FREDERICK T. ROBERTS.**

CHEST, Examination of. See **PHYSICAL EXAMINATION**.

CHEST-WALLS, Morbid Conditions of.—The walls of the chest may be the seat of various morbid conditions, and the affections

of this portion of the framework of the body demand more attention than they are accustomed to receive. All that can be done within the limits of this article is to indicate their nature; to notice briefly such of them as are not described in other parts of this volume; and to point out the principles of treatment. They may be considered according to the following arrangement:—

1. *Superficial Affections*.—Under this group may be included morbid conditions of the skin and subcutaneous tissues. *a.* Cutaneous eruptions are of common occurrence over the chest. Among these may be specially mentioned the eruptions of the exanthemata, herpes zoster, and chloasma. *b.* The superficial vessels are liable to become enlarged under certain circumstances. This enlargement is usually seen in the veins over the front of the thorax, which may be distended on both sides, or only on one side, or in some particular region. The larger divisions may alone appear to be involved; or a more or less extensive network of smaller veins may be visible, and occasionally even the capillaries seem to be implicated. This condition generally arises from some obstruction interfering with the circulation through one or other of the principal veins which, either directly or indirectly, receive the blood from the veins of the thoracic wall. Thus the superior vena cava, or either innominate, subclavian, or axillary may be implicated, being, for example, pressed upon by new growths or enlarged glands, the distribution and extent of the venous distension varying accordingly. Occasionally one of the smaller veins is thus interfered with. The writer has met with cases in which considerable enlargement of the veins was visible over portions of the thorax, where the cause was by no means evident, the patients asserting that this condition had existed ever since they could remember, and being regarded by them as perfectly normal. Probably it has resulted from some local obstruction occurring during early life. It must be remembered that women who are suckling frequently present great enlargement of the superficial veins over the front of the chest, which usually subsides when the period of lactation is at an end. Again, more or less venous and capillary engorgement in this region may occasionally be observed in cases of cardiac or pulmonary disease, where the general circulation is much impeded, and due aëration of the blood is interfered with. Sometimes a ring of enlarged veins and capillaries is seen around the lower part of the chest. When the venous distension is due to obstruction of the vena cava superior, the skin may present a more or less marked cyanotic tint, and in cases of general cyanosis, the chest, in common with other parts, has a cyanotic appearance. Occasionally one or other of the small arteries which supply the thoracic walls is enlarged, and it may attain a considerable size. *c.* Subcutaneous oedema is sometimes observed over the chest. In most instances this is a local condition, being the result of venous obstruction; but it may be a part of general dropsy, particularly in connexion with renal disease. This morbid state is evident on inspection or to the touch, and the affected part pits on pressure. *d.* The subcutaneous tissue of the thorax is also liable to become the seat of

so called emphysema, as the result of perforation or rupture of the lung and pleura, with the consequent escape of air into the cellular tissue under the skin, where it accumulates, and travels to a greater or less extent over the body. The lung may also give way into the mediastinum, the air which escapes subsequently making its way from this part into the subcutaneous tissue. This condition is generally due to direct injury, especially from fractured ribs, but it may also arise, in exceptional instances, from other causes, such as violent cough, powerful expiratory efforts, as in parturition, pulmonary disease—for instance, the giving way of a cavity in the lung—or in connexion with emphysema. Subcutaneous emphysema is attended with evident swelling of the part, which may be very great, all the normal anatomical outlines being obliterated; the peculiar sensation accompanying this condition is readily elicited on palpation and percussion; the percussion sound is tympanitic; and on auscultation a superficial crackling sound is heard. *c.* As belonging to the superficial affections connected with the chest may be just mentioned diseases of the mammary gland or nipple, which of course constitute a most important class of diseases in females (see BRAST, Diseases of).

2. Muscular and Tendinous Affections.

a. The muscles of the chest or their tendinous attachments may be the seat of certain painful affections. These are of the nature of so-called muscular rheumatism or myalgia, of inflammation, or of more or less injury or strain; being induced by cold, constitutional conditions such as gout, overwork, straining, violent coughing, fatigue from prolonged sitting, and other causes. The painful condition is usually localized, but different muscles are involved in different cases, sometimes those which are superficial being affected, in others the deeper muscles including the intercostals; or the complaint may be confined to a single muscle. Pleurodynia, dorso-dynia, and scapulodynia are the terms applied to muscular rheumatism affecting the side of the chest, the upper part of the back, and the scapular regions respectively. As the result of severe coughing, muscular pains are very common around the lower part of the chest. The pain is usually more or less aching in character, and not severe, but it may be very intense, especially in acute cases. Whatever brings the affected muscles into play aggravates the suffering, such as moving the arms or shoulders when the superficial muscles are affected, coughing, sneezing, and similar actions. In some instances the pain is not felt when the affected structures are kept quite at rest. There may be local tenderness on pressure, or diffused pressure may give relief, while posture often influences the sensations experienced, such as whether the patient assumes the recumbent or sitting posture, or lies on one or other side. Fatigue generally increases the pain. Muscular affections connected with the chest are not necessarily accompanied with any other local symptoms; and physical examination reveals nothing, except that perhaps the act of breathing is voluntarily restrained, on account of the pain thus induced. *b.* The muscles of the chest may be affected, on the one hand, with spasm or cramp; on the other, with paralysis. The former is attended

with more or less pain, which may be very severe; the latter is indicated by loss of power in the muscles involved. These disorders generally depend on some lesion of the central nervous system, but may result from local nervous disease. In cases of hemiplegia from cerebral mischief, the muscles of the thorax on the affected side are often temporarily weakened, but they usually subsequently regain their power. When the upper part of the spinal cord is injured or diseased at a certain point, all the muscles of the chest become paralyzed, which is a very serious matter, as respiration and the acts connected therewith cannot be carried on, except by the diaphragm, and consequently the blood is imperfectly aerated, secretions accumulate in the lungs, and the patient dies from suffocation. *c.* Atrophy or degeneration may involve the thoracic muscles. In cases of pulmonary phthisis either the whole of these muscles or certain of them are not uncommonly wasted out of proportion to the general emaciation. These muscles may also be more or less implicated in progressive muscular atrophy, and occasionally a single muscle undergoes marked wasting. The writer has seen a striking example of this local atrophy in connection with the pectoralis major, but the serratus magnus or other muscles may be implicated. The wasting is probably in most cases due to disease of the nerves supplying the affected muscles. It is quite evident on examination, and the movements which are usually performed by the involved structures cannot be executed properly. *d.* On the other hand, the chest-muscles may become hypertrophied. This may be a natural result of training; or it may occur in consequence of their being called upon, either habitually or at intervals, to act excessively, as in cases of emphysema or asthma. In exceptional instances the condition known as pseudo-hypertrophic muscular paralysis has extended up to the chest. *e.* The thoracic muscles occasionally present marked irritability under percussion or friction. This has been regarded as an important sign of phthisis; but the writer has only observed it in a comparatively few instances of this disease, and has found it equally if not more evident in cases where the lungs were perfectly healthy. *f.* As the result of injury and other causes, some portion of the muscular structures of the chest may be lacerated, ruptured, or perforated, either alone or along with other structures. This condition will be further alluded to presently.

3. Nervous Affections.—*a.* Neuralgia is very common in different parts of the chest, especially in the side, and particularly the left side—*intercostal neuralgia*. The pain is localized, being usually referred to a point where a branch of nerve becomes superficial. It is more or less constant, but subject to exacerbations, in some cases being very severe at times. It may be increased by deep breathing or coughing, but is not, as a rule, so much affected by these and similar actions as are other painful chest-affections. Shooting and darting sensations often radiate from the principal point, and certain spots of tenderness—*points douloureux*—may be recognised in many cases (see INTERCOSTAL

NERVE RIGID). *b.* Intercoastal neuritis is occasionally met with, and this affection is attended with great pain, localised and radiating, with much tenderness, the suffering being aggravated by whatever causes any local disturbance. It is probable that the severe pains experienced in some instances where the complaint is supposed to be muscular, are due to branches of nerve being in an inflammatory condition. *c.* Some individuals, especially females, exhibit a remarkable superficial tenderness over the thorax or in parts of this region, especially the anterior and upper portions. The slightest touch is resented, and the most delicate percussion cannot be borne. This condition may exist without any actual disease, or it is sometimes observed in phthisical cases. *d.* Sensation may be more or less impaired over the chest, or in limited portions, either in connexion with central or local nervous disease, or in hysterical and nervous persons. Various paresthesiæ are also frequently referred to this region by the class of individuals just mentioned.

4. Diseases of the Bones or Cartilages.—The morbid conditions which may be referred to the bony and cartilaginous framework of the thorax are as follows:—*a.* There may be undue rigidity and firmness of the chest-walls, owing to an excessive deposit of calcareous matter in the sternum and ribs, with ossification or petrification of the cartilages. This is a normal condition in old people, being one of the degenerative changes to which they are liable, but it may also occur in younger individuals, as the result of hard work, or in connexion with certain pulmonary diseases. This state of rigidity interferes more or less with the respiratory movements, and not infrequently causes serious embarrassment. *b.* On the other hand, the ribs and cartilages may be deficient in firmness, and consequently too yielding and elastic. This is observed in children and young persons who are ill-nourished, and it becomes a condition of great moment when any disease sets in which causes obstruction to the entrance of air into the lungs, such as bronchitis. The chest-walls are then liable to fall in more or less during the act of inspiration, and may become permanently deformed, the pigeon-breast and other abnormal forms of thorax being thus originated. In rickety children the vicinity of the junction of the ribs with their cartilages is the most yielding part of the chest, where nodular thickenings may often be felt, and in such subjects this is the portion of the thoracic wall which is most liable to fall in. *c.* Acute or chronic periostitis or perichondritis is sometimes observed in connexion, respectively, with the sternum or ribs, or with the cartilages. The acute affection gives rise to much pain and tenderness, which may be accompanied with superficial redness and swelling, and may simulate some more serious disease. The chronic complaint usually assumes the form of a node, being the result of syphilis. The writer has occasionally observed a small swelling at the junction of one of the ribs with its cartilage, painless, unaccompanied with redness, but presenting distinct fluctuation. *d.* The bony and cartilaginous structures themselves may be the seat of disease in some part of

the chest, and here must be included the portion of the spinal column which limits this region posteriorly. Thus there may be acute inflammation, caries, necrosis, or so-called scrofulous disease. Among the more important causes which are liable to originate these conditions may be mentioned injury, syphilis, scrofula, empyæma opening externally, and thoracic tumours or aneurisms growing outwards. They may lead to serious consequences, both local and general, and frequently cause more or less deformity of the chest. *e.* Permanent thickening and distortion of portions of the ribs are sometimes observed after fractures which have united improperly.

5. Inflammation and Abscess.—It is expedient to make a separate group of those cases in which inflammation, resulting in the formation of one or more abscesses, occurs in some portion of the soft structures entering into the construction of the chest-walls. This may be of local origin, arising from injury, bone-disease, or other causes, or it may be due to the opening of an empyæma into the tissues; to suppuration extending and burrowing from the axilla or other parts, or to pyæmia. If deep-seated, an abscess may be difficult to detect with certainty, but usually the signs of this condition become sufficiently obvious. Sinuses or fistulæ may be left as a consequence of suppuration in the chest-wall, especially when pus makes its way outwards from within.

6. Tumours and New-Growths.—These morbid conditions also demand separate notice. They may be connected with any of the structures of the chest-walls, and are of various kinds; among those which have come under the writer's notice may be mentioned molluscum, fatty growths, cystic tumours, enlarged sebaceous glands, and infiltrated carcinoma. Tumours may make their way inwards from the chest-walls, encroaching upon the cavity of the thorax; or, on the other hand, the walls may be involved by growths from within. It need scarcely be mentioned that mammary tumours constitute a distinct, and by far the most important group associated with the structures covering the chest. See BREAST, Diseases of.

7. Perforations and Ruptures.—The muscular structures of the thoracic wall may be more or less destroyed in some part either by sudden rupture or gradually, allowing a hernial protrusion of the lung to take place between the ribs. As already noticed, empyæma may make its way outwards through the chest-wall. Aneurisms and tumours extending outwards from within the thorax frequently cause serious destruction of the tissues, including the bony and cartilaginous, as well as the soft structures. This destructive process is often attended with severe pain and suffering, and leads to grave mischief.

8. Variations in Form and Size.—The chest often presents deviations from the normal shape and size, and these are so important that they demand separate consideration. See DEFORMITIES OF CHEST.

TREATMENT.—In many cases where the chest-walls are in a morbid state, they either do not need any special treatment, or no treatment

be of avail. The chief circumstances under which the practitioner may be called upon to interfere, and the measures to be adopted, may be briefly indicated as follows:—

a. Painful affections of the chest-walls, depending upon conditions of the muscles or nerves, frequently demand local applications for their relief. Thus in different cases it may be requisite to employ hot fomentations, dry heat, or cold applications, in the form of wet rags frequently changed, ice, or evaporating lotions; or to use anodyne applications of various kinds, such as belladonna plaster or liniment, opium plaster or a liniment containing laudanum, oleate of morphia, tincture of aconite or ointment of aconitine, or veratria ointment. Anodynes may also sometimes be added to fomentations with advantage. Friction is often of much service, and at the same time stimulating liniments may be employed, such as one containing camphor, chloroform, or turpentine. For ill-defined muscular pains about the chest, which are frequently complained of, free douching with cold water every morning, followed by friction with a rough towel, is often highly efficacious. When pain is localised and obstinate, much benefit may be derived from the application of a sinapism, mustard-leaf, or even a small blister. In other cases the use of the ether-spray is serviceable, repeated more or less frequently; or sometimes much relief may be obtained from applying over a painful spot a mixture of equal parts of chloroform and belladonna liniment. Galvanism is another agent which may be of the greatest service in relieving painful sensations about the chest, whether connected with the muscles or nerves. Subcutaneous injections of hot water, morphia, or atropine may be demanded in some cases, and constitute a most valuable mode of treatment if pain cannot otherwise be assuaged.

In the treatment of many painful affections of the chest-walls much assistance may be derived from attention to posture, especially in connection with certain occupations, from the avoidance of undue fatigue, or of any violent actions which are known to influence this part, such as cough, and from the adoption of measures tending to support the structures, or to keep them in a state of rest. The writer has found great benefit in a large number of instances from strapping the side more or less extensively, in the manner advocated by him for the treatment of pleurisy, and if there is any localised pain, some limited anodyne application, such as a piece of belladonna plaster, may be placed over this spot under the strapping.

b. In many affections of the chest-walls, treatment directed to the general system, or to some special constitutional condition, is often of the greatest service. Thus, in the painful complaints already noticed, there are frequently marked general debility and anaemia; and essential benefit is derived from the administration of quinine, preparations of iron, strychnine, cod-liver oil, preparations of phosphorus, and other tonic medicines, or such as improve nutrition. Some of these are also most useful when there is disease of bone and its consequences. Again, certain affections of the thoracic wall may be associated with rheumatism, gout, or syphilis, and then the

particular treatment indicated for each of these several conditions is called for.

c. When disorders of the muscles of the chest-walls occur, such as paralysis or spasm, associated with some disease of the central nervous system, the treatment must usually be directed to this disease, and but little can be done for the local disturbance. In some instances, however, electrical or other modes of treatment may be of some service, by influencing the action of the muscles, but no definite rules can be laid down.

d. Local inflammations in connection with the thoracic walls must be treated as in other parts of the body, and it is unnecessary to discuss this subject in the present article.

e. Surgical treatment may be called for under certain circumstances. Of course this will be the case if the chest-walls are injured in any way. Among other conditions likely to demand surgical interference may be specially mentioned subcutaneous emphysema, abscesses, disease of the bones, and tumours.

FREDERICK T. ROBERTS.

CHEST-WALLS, Deformities of. See DEFORMITIES OF CHEST.

CHICKEN-POX.—SYNON.: Varicella; Fr. *La Varicelle*, Ger. *Wasserpocken*.

DEFINITION.—A specific infectious febrile disease, characterised by the appearance, in successive crops, of red spots, which in the course of about a week pass through the stages of pimple, vesicle, and scab.

ÆTIOLOGY.—The origin of this disorder is unknown. It is certain that it arises from contagion, and that childhood is its predisposing cause. It occurs in children at the breast, and is seen with increased frequency up to the fourth year, at which period it attains its maximum. It is less often found between four and twelve, and after twelve it may be said to disappear, although it is occasionally seen in adults.

SYMPTOMS.—The illness commences without any, or with but slightly-marked premonitions. There is usually, however, some feeling of lassitude, and the patient goes to bed earlier than usual. Within a few hours an eruption appears, usually on some part of the back or chest, but there are many exceptions to this rule. It may commence on the face, neck, chest, abdomen, or extremities, or upon several of these parts at the same time. The eruption consists of small, faintly papular rose-spots, varying in number from twenty to one or two hundred. These, in the course of eight, twelve, or, at the most, twenty-four hours from their appearance, change into vesicles, which, at first small in size and clear as to their contents, become quickly large; globular, or semi-ovoid in form, translucent, glistening, and opalescent in appearance; and surrounded with a faint areola. Towards the end of the second day of illness, the vesicles attain complete development, and about this time a few may be seen on the sides of the tongue, on the lips, cheeks, or palate, and sometimes upon the mucous membrane of the genitals. About the third day a few of the vesicles may have a pustular appearance, and sometimes a few pustules are seen; but, regarding the eruption as a whole, pustulation forms an incident rather than an essential feature

in its progress. On the fourth day the vesicles begin to dry up, and by the sixth complete scales are formed. These fall off in a few days, leaving in their place faintly red spots, and sometimes a few pits. A single crop of the eruption may be said to complete itself in five or six days; and as two or three crops appear on as many successive days, the illness will last rather more than a week. In the event, however, of there being four or five crops, it may be prolonged for another week, but this is unusual. With the appearing of the eruption, the temperature rises two, three, or even more degrees, and this rise recurs with each successive crop of spots. The pulse is sometimes slightly increased in frequency; the tongue is moist, and sometimes covered with a light fur. As a rule, however, there is but little constitutional disturbance, although it is occasionally severe.

PATHOLOGY.—Chicken-pox is due to the reception of a specific poison, which after an incubation of about thirteen days, shows itself by an eruption upon the skin. What this poison is, how it enters the body, and what, if any, changes it produces upon the internal organs, the present state of our knowledge does not enable us to say. It affects the same individual once only, and it is perfectly distinct from modified small-pox, as the following considerations will show:—

1. Chicken-pox is characterised by the *rapidity* with which it runs through its stages; modified small-pox, on the contrary, is characterised by an interruption in the course of the disease at one or other of three points—the papular, the vesicular, or the pustular. 2. The chicken-pox eruption attains complete development by the end of the third day; in modified small-pox, should the eruption attain complete development, this will not occur before the ninth day, however much the disease may be modified. 3. In modified small-pox the premonitory symptoms are usually well-marked, often quite as severe as in the natural disease, and these last forty-eight hours, after which there is an eruption of small hard papules on the forehead, face and wrists, followed by a *fall* of temperature. In chicken-pox the premonitories are most often wanting, and when present are slightly marked, and the eruption is followed by a *rise* in the temperature. It appears, moreover, upon any part of the body indiscriminately, and less frequently on the face than on other parts; and within a few hours—at the most within twenty-four—it has become vesicular; whereas in modified small-pox the vesicular stage is only reached forty-eight hours after the appearance of eruption. 4. The vesicles of chicken-pox are globular or ovoid in form, without any central depression; glistening or translucent in appearance; and unicellular in structure. They collapse on pricking, and attain their maximum development in from twelve to eighteen hours. Modified and natural small-pox vesicles are flat and circular in form, always depressed in the centre, and sometimes umbilicated, of an opaque dirty white colour, and multicellular in structure. They do not collapse on pricking, and attain their maximum development at the end of the third day from their origin. 5. Small-pox is an invariable affection; chicken-pox, according to reliable authority, is not. 6. When cases arise

which all recognise to be modified small-pox, they are always accompanied by others which are more severe; and in epidemics these latter gradually become more numerous up to a point of maximum intensity, when they decline and the modified forms reappear. In chicken-pox there is no such gradual increase in the intensity of illness, and neither serious nor fatal cases form part of its epidemics, which prevail independently of small-pox. 7. Small-pox and vaccinia are often early followed, in the same individual, say within two or three years, by chicken-pox, and *vice versa*. 8. Chicken-pox, vaccinia, and small pox have been known to follow in immediate succession in the same individual.

COURSE, TERMINATIONS, SEQUELÆ.—Varicella always runs a favourable course, invariably terminates in recovery, and has no sequelæ.

DIAGNOSIS.—It should be borne in mind that a sure diagnosis cannot be made in less than forty-eight hours. The appearance, however, of a crop of vesicles, followed on the next day by a second crop, points almost certainly to chicken-pox. Attention to this, and to the points noted under the head of pathology, ought to make the diagnosis easy.

PROGNOSIS.—This, as has been indicated above, is always favourable.

TREATMENT.—The treatment of chicken-pox consists in confining the patient to his room, or in the more marked cases to his bed, for one or two days, and in the administration of light, unstimulating food. Although no physician has recorded a fatal case of chicken-pox, a child whose temperature may be three, four, or six degrees above the normal, should be watched with care.

ALEX. COLLIER.

CHIGOE.—**DESCRIPTION.**—The Chigoe is a minute parasitic insect, common in the West Indies and northern parts of South America. It is also popularly known as the *Jigger* or *Sandflea*. Though formerly regarded as an acarus or mite, it is now generally recognised as a true flea belonging to the genus *Pulex* (*P. penetrans*); but several entomologists have advanced solid reasons for separating it from the ordinary fleas. Thus Westwood terms it the flesh-flea, or *Sarcopeylla penetrans*, whilst Guérin formed the genus *Dermatophylus* for its reception. Practically, these distinctions are of little moment.

The Chigoe ordinarily lives in dry and sandy situations, where it multiplies to a prodigious extent. It attacks, however, the feet, chiefly underneath the nails and between the toes; the impregnated females burying themselves beneath the skin. Here the abdomen of the parasite swells to the size of a pea; and, unless removed by operation, gives rise to acute local inflammation, terminating in suppuration and sometimes in extensive ulceration, with even fatal results to the patient. Dogs also suffer excruciating torment from the bites and immigration of the *Bicho do Cachorro*, which, however Pohl and Kollar regard as distinct from the human jigger (*Bicho de pé*). Be that view correct or not, it would appear from the observations of Rodachild and Westwood that the larvae of the human chigoe are hatched in the open wounds or ulcers, which sometimes extend inwards so as to involve the lumæ

themselves. In bad cases amputation of the toes and adjacent parts becomes necessary. Left to themselves, the larvae escape from their host, and probably, after the manner of bots and other parasitic insects, penetrate the soil for the purpose of acquiring the pupal stage of growth.

TREATMENT.—As regards treatment, the indications are simple. The parasite should be removed with the utmost care. Where this has not been done, and where, as a consequence, open sores exist, frequent washings with tepid water, followed by the application of carbolic acid lotions (twenty or thirty grains to the ounce), or of ointments (one drachm to one ounce of benzoated lard) will be found most suitable. Or, again, the carbolic acid putty, as sold in shops, or the application of one part of the acid previously mixed with ten or twelve parts of simple olive oil, will, in all likelihood, be sufficient to cause the destruction of any larvae that might remain. In European practice cases of jigger are rarely seen; nevertheless the writer has recorded an instance in which strong mental delusions followed the torture produced by these creatures (*Worms*, p. 141). The patient, a middle-aged married lady, had suffered severely during her residence in the West Indies. Although she had got rid of the parasites, she constantly harpooned her own feet in the hope of destroying the young jiggers which she felt were still burrowing beneath the skin. Lastly, it seems almost needless to say that residents and travellers in Guiana, Brazil, and in the West Indies generally, should have their feet properly protected. T. S. CORRIE.

CHILBLAIN.—**SYNON.**: Kibe; *Pernio*; Fr. *Engelure*, Ger. *Frostbeule*.

DEFINITION.—A state of inflammation of a part of the skin induced by cold.

ÆTIOLOGY.—Chilblains are common in children and young persons, and are more frequent in girls than in boys. They occur chiefly in those of a lymphatic constitution, and may be considered as an indication of debility and deficient vital power. In adult age they are rare, and are only met with when the powers of the constitution are reduced. Their occurrence is influenced more by the strength of the individual than by the degree of cold, and they continue in some persons throughout the entire year. Their tendency is to cease with the full development of the organism, and they reappear occasionally in advanced life.

DESCRIPTION.—The regions of the body usually affected with chilblain are the feet and hands, to which are sometimes added the ears and nose. A chilblain presents three stages or degrees of severity, namely, *erythematous*, *bullous*, and *gangrenous*; and it may be arrested at the first or second stage by the withdrawal of the cause. The *erythematous* stage is restricted to hyperæmia, swelling, and severe burning and itching, the itching being increased by heat, as by that of the fire or that induced by exercise. The congested spot is circular in figure, somewhat tumid, brightly red at first, but later on roseate crimson, purple, or livid in colour. The second or *bullous* stage exhibits the blain or blister resulting from effusion of serum beneath the cuticle; the permanent colour of the swelling is

now purple or livid, and the contents of the blister a limpid serum, generally reddened with blood; sometimes, indeed, the fluid of the blister may be semi-purulent. In the *gangrenous* stage the blister is broken, the surface of the derma is in a state of gangrene, and the gangrenous layer is subsequently removed as a slough by ulceration.

TREATMENT.—The treatment of chilblain requires to be modified to suit its different degrees. In the first, the indication is to restore normal circulation by gentle friction, and, when the part is severely chilled, it is usual to rub it with snow; then some soothing liniment may be employed; and, finally, a stimulating liniment, covering the part afterwards with zinc ointment and cotton wool, or shielding it with lead or opium plaster spread on washleather. The liniments most in favour for this purpose are the soap liniment with chloroform, the compound camphor liniment, the turpentine liniment, and the linimentum iodi. In the bullous stage a similar treatment may be used to the erythematous portions, whilst the blister should be snipped and the broken surface pencilled with the compound tincture of benzoin, and afterwards dressed with unguentum rosine or an ointment of Peruvian balsam. In the third stage the erythematous phenomena still require attention, and the ulcer should be dressed with unguentum rosine, either alone, or in combination with spirits of turpentine.

To obviate constitutional debility, the diet should be nutritious and generous, and recourse may be had to tonic remedies, such as iron and quinine. ERASMUS WILSON.

CHILL.—A subjective sensation of coldness, accompanied with shivering, and most frequently experienced in connexion with febrile or inflammatory diseases, in nervous individuals, and after exposure to cold and wet. In popular language 'taking a chill' is used as synonymous with 'catching a cold.' See RIGOR.

CHIN-COUGH.—A synonym for whooping-cough. See WHOOPING COUGH.

CHIRAGRA (χείρ, the hand, and ἔγγρα, a seizure)—Gout in the hand. See GOUT.

CHLOASMA (χλόα, a green herb).—**SYNON.**: Liverspot. Fr. *Ephélide*; Ger. *Lebersfleck*. A pigmentary discolouration of the skin, of a yellowish brown or liver-colour tint, occurring in blotches, and due to constitutional causes. Its synonym, *ephelis gravidarum*, indicates its occasional association with pregnancy. See PIGMENTARY SKIN DISEASES.

CHLOROFORM, Use of. See ANÆSTHETICS.

CHLOROSIS (χλωρός, green or sallow). **SYNON.**: Green-sickness; Fr. *La chlorose*; Ger. *Chlorose*; *Blacksucht*.

DEFINITION.—A variety of anæmia occurring in a peculiar diathesis or habit of body, which is characterised by deficient growth of the corpuscular elements of the blood, and of the vascular system.

The subjects of this diathesis are said to be *chlorotic*. They ordinarily enjoy good health, unless exposed to any of the causes of anæmia, when they speedily suffer from aglobulism; and this aglobulism may proceed to complete anæmia. The term *chlorosis* is properly applied to the first and simpler form of anæmia in these subjects; while the second and more complex condition is designated *chlor-anæmia*; or, more commonly, *anæmia* (see ANÆMIA).

ÆTIOLOGY.—Chlorosis occurs almost without exception in young women about the time of puberty, but is found occasionally in children and married women, and, very rarely, even in men. It is believed to be more common in the higher ranks of life. Beyond these predisposing causes, however, the very origin of the disease lies in a peculiar condition of the blood and blood-vessels, to be presently described, which is believed to be congenital, and perhaps hereditary. In such subjects, and under the preceding circumstances, any of the numerous causes of anæmia may be sufficient to excite the appearance of chlorotic symptoms, but those which do so most commonly are sexual development, the establishment of menstruation and its disorders, and an insufficient supply of light to the circulating blood.

ANATOMICAL AND CHEMICAL CHARACTERS.—The blood in chlorosis presents three definite and distinct imperfections. First, the total quantity of blood is below the normal, though there may be an excess in relation to the calibre of the vessels (*plethora ad vasa*). Secondly, both red and white corpuscles are deficient in numbers, and that proportionately. Thirdly, the individual red corpuscle contains less than the normal amount of hæmoglobin, and this deficiency may be so great that the total amount of hæmoglobin in the blood is reduced to one-fourth. It is an important negative fact that in pure chlorosis the quality of the liquor sanguinis is unchanged.

With this condition of blood there are associated remarkable abnormalities of the aorta and arterial system generally. The most striking of these is a hypoplasia, or dwarfed condition of the aorta, represented by small calibre, increased elasticity, anomalous origin of the branches, and unequal thickness of the intima. Along with these there may be found—probably as a consequence of the preceding—fatty metamorphosis of the intima, and enlargement of the heart, with traces of endocarditis. The blood-glands and lymphatic structures are not diseased. The condition of the ovaries and uterus has been carefully examined in chlorosis and found to vary extremely. In some cases the generative organs are described as ‘infantile,’ while in others they are either immoderately developed, or perfectly normal in every respect. Corresponding with the aglobulism, the subcutaneous fat is abundant; and the viscera present various degrees of fatty metamorphosis. When the cardio-vascular changes are marked and advanced, there may be extensive secondary disease throughout the body.

SYMPTOMS.—The symptoms of simple chlorosis are those of mild anæmia, with certain important differences, which become fewer and less

marked and finally disappear as chlorosis advances to the more serious disease. The appearance of the chlorotic girl is peculiar, inasmuch as the pallor of her complexion is accompanied by natural or even increased fulness, from the excess of subcutaneous fat. At the same time the colour of the skin is so remarkable as to have given the name to the disease, the general hue being decidedly yellow. In blondes the transparency of the skin is increased; in brunettes it is diminished, and a dull yellowish-grey colour of skin is the result, which, in contrast with the greyish-blue of the eyelids, may appear of a sickly green.

The patient's usual complaint is of this alteration of colour, menstrual disorder, debility, great breathlessness, cardiac symptoms, and various pains. The menstrual symptoms are always prominent, namely amenorrhœa or menorrhagia, and leucorrhœa. Breathlessness on exertion is one of the most striking symptoms. The cardiac symptoms and the cardiac and vascular signs closely resemble those of anæmia. But there is this important difference in the phenomena connected with the heart, that in many cases of chlorosis they indicate enlargement, and especially hypertrophy of the left ventricle. The digestive and nervous systems are frequently very seriously deranged. The urine is abundant, watery, and pale. There is no dropsy in simple, uncomplicated chlorosis. Optic neuritis may occur.

The *chlorotic diathesis* may be recognized by the following characters, which are variously associated in different cases:—Diminutive stature; imperfect sexual development; a history of peculiar anæmia in childhood, of anæmia with menstrual irregularity at puberty, and of previous attacks of symptoms of chlorosis; evidence of cardiac enlargement or mitral disease in the absence of all the ordinary causes of these; the occurrence of endocarditis during pregnancy or *post partum*; and the presence of any of the diseases which will be referred to under the head of *complications*.

COURSE, DURATION, AND TERMINATION.—The commencement of chlorosis is generally gradual, but may be sudden. Its ordinary course is towards confirmed anæmia, in which it may terminate, the liquor sanguinis becoming affected, and wasting and œdema being added to the previous symptoms, which are also aggravated. It is for this reason that pure chlorosis is a rare disease, while anæmia associated with the chlorotic diathesis is comparatively common.—The duration of the disease is variable; it rarely declines until the determining circumstances have been removed, and the patient subjected to careful treatment. Chlorosis may reappear in the subject of the diathesis, and that more than once; but the probability of its return is small after the age of 25, especially in the married female. Death from chlorosis directly is excessively rare.

COMPLICATIONS AND SEQUELÆ.—According to Virchow, serious valvular disease and cardiac enlargement may be traced in some of the worst cases of chlorosis to the associated vascular condition; and the mitral valve is peculiarly liable to be attacked by endocarditis in rheumatic,

peryspl, or septic fever. Hemorrhages, gastric ulcer, and exophthalmic goitre are believed to occur with comparative frequency in persons of the chlorotic diathesis.

PAATHOLOGY.—The deficiency of the blood in red and white corpuscles, and of the individual red corpuscle in hæmoglobin, described above, indicates an imperfect production of the cellular elements of the blood, and imperfect growth of the red corpuscles. With this blood-state there is undoubtedly associated a hypoplastic or dwarfish condition of the blood-vessels. In the embryo the blood and blood-vessels are developed from the same elements, the former making its appearance within the cells which produce the latter. It is highly probable, therefore, that the anomaly of blood and the anomaly of vessels are to be considered as together an expression of some congenital defect of the blood-vascular system, leading to imperfect growth both of blood and of vessels. Any individual possessing a blood-vascular system thus anomalous labours under a peculiar diathesis, or debility of the corpuscles and circulatory system, and is said to be a *chlorotic* subject.

If the other systems of the body are full-sized (which is not always the case) the dwarfish condition of the arteries of the chlorotic subject, and the scanty supply of hæmoglobin, will tend to fail to supply the ordinary demands for blood, and especially for oxygen, and at every period of extraordinary demand within the economy the blood-vascular system will be in danger of breaking down. Exposure to any of the causes referred to above will be sufficient to produce the symptoms of aglobulism, that is, chlorosis; and that when they would not affect the blood of an ordinary non-chlorotic individual. This effect is peculiarly striking when the exciting influence is one which is universally recognised as an important factor in the production of chlorosis, namely want of light; for light is essential in the formation of hæmoglobin, and to the health of the red corpuscle. Thus the special phenomena of uncomplicated chlorosis are those of aglobulism or deficiency of the oxygenating substance of the organism; and they furnish one of the purest examples in the whole range of pathology of the effects of want of oxygen in the system (see *Blood, Morbid Conditions of*). When chlorosis advances to anæmia, by the implication of the plasma, a new series of phenomena present themselves, prominent among which are loss of flesh and œdema of the extremities.

The relation of the cardiac enlargement and valvular disease to the vascular hypoplasia is a purely physical one. More complex is the connexion between the blood-vascular condition and that of the generative organs. The chlorotic diathesis, or actual chlorosis, will manifestly interfere with the development and activity of the ovaries and uterus; whilst, on the other hand, disorders of the sexual functions are amongst the most frequent exciting causes of aglobulism.

DIAGNOSIS.—Chlorosis is to be distinguished from symptomatic and idiopathic anæmia; and the points by which the diagnosis may be accomplished have been sufficiently indicated above. Leukæmia may be readily recognised

by a careful examination of the blood and spleen.

PROGNOSIS.—The prognosis is highly favourable as regards life; and a speedy cure may be assured in uncomplicated cases subjected to careful treatment.

TREATMENT.—The success of a particular method of treatment of simple chlorosis is one of the strongest arguments in favour of the correctness of the preceding view of the pathology of the disease. The condition being one of aglobulism, the treatment employed will be so far simpler than that of anæmia, that the red corpuscles alone have to be restored. While the various measures recommended in the more serious blood-disorders are therefore to be employed, if necessary, it will generally be found that in chlorosis iron alone will be sufficient to effect a cure. The particular form in which the drug is to be presented must be carefully selected according to circumstances which need not be repeated in this article. A free supply of sunlight is essential, and must be insisted upon; and physiological rest of the blood and of the organs of circulation is equally necessary.

J. MITCHELL BRUCE.

CHOLAGOGUES (χολή, bile, and ἀγω, I move).—**DEFINITION.**—Substances which lessen the amount of bile in the blood.

ENUMERATION.—The principal cholagogues are Mercury and its preparations—especially calomel and blue pill; Podophyllum and Podophyllin, Aloes, and Rhubarb.

ACTION AND USES.—The liver has a two-fold action—it forms bile, which is poured into the duodenum; and it also excretes the bile which has been reabsorbed from the duodenum and carried back to the liver by the portal circulation. Much bile thus circulates continually between the liver and duodenum, while part is carried down the intestine with the feces, and its place supplied by newly-formed bile. When the quantity circulating in this way is too great to be completely excreted by the liver, it enters the general circulation and produces symptoms of *biliousness*. These are removed by the so-called cholagogues, which probably act by stimulating the duodenum, and thus carrying the bile so far down the intestine as to interfere with re-absorption. Amongst the best cholagogues are the preparations of mercury, which do not increase the secreting power of the liver, nor augment the quantity of bile formed by it. Their utility is greatly increased by combination with a saline purgative, which still further clears out the intestine, and completely prevents any re-absorption of bile. Other cholagogues, such as podophyllin, rhubarb, and aloes, actually increase the secretion of bile by the liver. At the same time, they probably prevent its re-absorption, in a similar way to mercurials and salines.

T. LAUDER BRUNTON.

CHOLELITHIASIS (χολή, bile, and λίθος, a stone).—The condition of system associated with gall-stones. See *GALL-STONES*.

CHOLERA, ASIATIC.—**SYNON.**: *Serme cholera*, *Symptomatic cholera*, *Malignant cholera*, *Fr. Choléra asiatique*, *Ger asiatische Cholera*.

DEFINITION.—Asiatic cholera is a specific disease, characterised by violent vomiting and purging, with rice-water evacuations, cramps, prostration, collapse, and other striking symptoms; tending to run a rapidly fatal course; and capable of being communicated to persons otherwise in sound health, through the dejects of patients suffering from the disease. These excreta are most commonly disseminated among a community, and taken into the system by means of drinking water, or in fact by anything swallowed which has been contaminated by the organic matter passed from cholera patients. In badly ventilated rooms the atmosphere may become so fully charged with the exhalations from patients suffering from cholera as to poison persons employed in nursing the sick. In the same way people engaged in carrying the bodies of those who have died from cholera for burial, or in washing their soiled linen, may contract the malady. In a dried condition the organic poison contained in cholera excreta may retain its dangerous properties for a long time.

The disease is endemic in certain parts of British India, where from time to time it assumes a virulent type, and is apt then to spread, through the means above indicated, along the great lines of human intercourse, and so to extend over the world.

HISTORY.—Since the days of Hippocrates medical practitioners residing in various parts of Europe have described a disease which they called cholera. The nosology of this affection was hardly a matter of doubt with them, and it is only in modern times that the question has arisen as to whether the cholera commonly met with among us is identical in its nature with Asiatic cholera. Doubtless, if we compare isolated cases we may find that the symptoms which these affections induce are very similar; but those who have lived beyond the endemic area of Asiatic cholera, and watched the disease spread from India over Europe and America, can scarcely mistake this malignant malady for simple cholera. Asiatic cholera was unknown in Europe before the year 1829-30, although it has existed in India for many centuries. It is true we have no accounts of cholera extending throughout the whole of Hindustan prior to the year 1817, but this arises from the circumstance that it was only at the commencement of the present century that the British Government began to bind the heterogeneous principalities of India into union, and thus render it possible for us to gather together authentic details regarding the disease as it spreads from one province to another.

We cannot here fully consider the relations which unquestionably exist between the rapidity of the diffusion of cholera from the East over Europe, and the increased facilities of communication that have lately been established between India, and Persia, and Arabia, also from Hindustan to Russia, and the shores of the Mediterranean. For instance, forty years ago the passage from Bombay up the Arabian and Persian Gulfs could only be undertaken at certain seasons of the year when the winds were favourable, and even then the voyage was tedious and most difficult to accomplish; now

large steamers run every week from Bombay to Bassorah and the intermediate ports along the Persian Gulf, and others pass with equal rapidity to the various towns bordering the Red Sea. But, although we cannot enter further into this subject, we must, in order to appreciate the nature of cholera, glance at the chronological order of some of the principal outbreaks of the disease which have been disseminated from British India over the world.

In 1817 cholera spread rapidly throughout Bengal; extending during the following year over the greater part of Hindustan, and from thence to Ceylon, Burmah, and China. The disease was communicated from Bombay *via* the Persian Gulf in 1820-21, and travelled northward, but did not extend into Europe.

During the year 1826 cholera again burst out over Bengal, and passing through the Punjab, it entered Calcutta in 1828, and from thence extended to Persia, and so to Russia during the years 1829-30, and over the whole of Europe and the greater part of America.

In 1840-41 cholera accompanied a British force despatched from Calcutta to China; it broke out among our troops on their voyage to that country, and having spread throughout the Chinese and Burmese empires, it passed in 1843-44 through Kashgar to Bokhara, and so to Calcutta. From Afghanistan the disease extended south into Scinde, and westward in 1845-46 through Persia to Russia and Europe, reaching America in 1848.

In 1849 cholera was very fatal over Bengal, and during the season of 1851-52 it was communicated through the Punjab and Bombay respectively to Persia and Arabia, and in 1853-54 it spread *via* Russia and Egypt with frightful virulence throughout Europe and America.

During the years 1860-61-62 cholera prevailed to an alarming extent throughout Bengal and the Central Provinces, and in 1864-65 in Bombay and along the shores of the Red Sea; thence it passed with pilgrims from Mecca to Egypt, and so to Europe, and for the fourth time to America.

These various outbreaks of cholera were usually remarkably sudden in their advent, a considerable number of people in the affected locality being attacked by the disease within a few days after it appeared among them. The malady almost invariably died out from amongst the inhabitants of a country under its influence during the cold seasons of the year, to re-appear on the approach of summer. As a general rule the disease was most deadly during the first year of the epidemic; it decreased in violence the second season; and then gradually disappeared, seldom prevailing in any one locality for more than three consecutive years.

ÆTIOLOGY.—The more we study the history of Asiatic cholera the better shall we understand that every outbreak of the disease which has occurred beyond the confines of India might invariably be traced back through a series of cases to that country; the disease has never broken out spontaneously in any other part of the world—no amount of filth, bad food, or climatic influences have up to the present time induced a widespread epidemic of cholera. The inhabitants of some

tries far removed from Hindustan, and having limited communication with that empire, such as Australia, have not experienced the disease; whereas those states which have been brought into intimate relation with India have become frequently subject to outbreaks of cholera.

Many of the earliest Anglo-Indian authors declared their conviction that the disease was contagious; others disputed this idea, but all agreed that cholera when extending over a country often settled on the inhabitants of low-lying, ill-drained, and overcrowded localities, and that it frequently left unharmed people residing beyond the affected area, although they might have been employed in attending patients suffering from the disease. It remained for Dr Snow, in 1854, to explain this apparent mystery, and to demonstrate, as he did by means of the Broad Street case, that the poison which causes cholera is contained in the excrements of those suffering from the disease, and 'that if by leakage, soakage from cesspools or drains, or through reckless casting out of slops and wash-water, any taint, however small, of the infective material gets access to wells and other sources of drinking water, it imparts to enormous volumes of water the power of propagating the disease' (Simon). Cholera patients cannot, in fact, communicate the affection to others, unless by means of the discharges which they pass. Persons attending them run no risk of contracting the disease provided they are protected from swallowing the organic poison passed by the sick; but in badly ventilated rooms, this organic matter having been disseminated in considerable quantities through the atmosphere, may be taken into the system by attendants, and so poison them.

Dr. W. Aitken observes that the evidence in favour of the communicability of cholera by means of water or food contaminated with cholera dejecta has since 1854 become almost overwhelming. A remarkable instance of the kind reported by Mr. N. Radcliffe took place in East London during the year 1866; and previous to this time the circumstances of a case came under the writer's notice, in which a small quantity of a fresh rice-water stool passed by a patient suffering from cholera was accidentally mixed with some four or five gallons of water, and the mixture exposed to the rays of the tropical sun for twelve hours. Early the following morning nineteen people each swallowed about an ounce of this contaminated water—they only partook of it once,—but within thirty-six hours five of these nineteen persons were seized with cholera. In this instance the choleraic evacuation did not touch the soil: as it was passed, so was it swallowed, but (and this is most important to remember) it had been largely diluted with impure water, and the mixture had been exposed to the light and heat of a tropical sun for twelve hours.

Doubtless we have much yet to learn regarding the nature of the organic substance which causes cholera. Professor Pettenkofer holds that if this material after leaving the human body happens to pass into the ground, it may there, under peculiar conditions of soil, moisture, and heat, undergo definite changes, and then, having risen as a miasma into the air, may

poison those who are predisposed to the disease: the earth, according to this theory, seems called on to play the part in the rôle of cholera which has been assigned in former times to solar, lunar, electrical, or epidemic influences. The conclusions recently arrived at in Bengal by Drs. Lewis and Cunningham rather incline towards this view. The difficulty of working out these problems in relation to the infecting material of cholera is enhanced by the fact, that the human is the only animal which is uncontestedly subject to its influence. We must, however, refer our readers to some admirable papers by Dr E. Parkes, published in the *Army Medical Department Reports*, for accurate knowledge on this subject.

Predisposing Causes.—Persons arriving in an infected area are predisposed to the disease. Beyond this fact nothing certain is known concerning the existence of predisposing causes of the disease.

ANATOMICAL CHARACTERS.—The external appearances of the bodies of those who have died of cholera present the mottled skin, shrunken and livid appearance of the limbs, and other features hereafter described as characteristic of the disease during the stage of collapse. The temperature of the body rises after death, and it remains warm for some time. Rigor mortis sets in speedily and is sometimes accompanied with muscular contractions, which displace the limbs of the corpse.

With regard to the internal lesions observed after death from Asiatic cholera, the writer's observations lead him to the conclusion, that almost the only alterations noticed in the tissues are due to the physical and chemical characters of the blood having been changed, consequent on its loss of water. The mucous surface of the stomach and small intestines is injected and swollen, and its epithelial cells contain micrococci; this epithelium drops off the surface of the mucous membrane in large patches within an hour and a half after death; and whatever may be the nature of the changes going on in the epithelial coat of the intestinal canal in cases of cholera, there can be no doubt as to its being extensively affected in this disease.

Anatomical changes of a specific nature, especially with reference to the amount of blood contained in the right side of the heart and lungs, have been described by pathologists as being characteristic of Asiatic cholera; and in many instances after death from this disease, if the post-mortem is delayed for a few hours, the right side of the heart will be found full of blood, together with the pulmonary artery and its divisions; while the lungs are collapsed and bloodless. But the writer holds that there are numerous exceptions to this state of the heart and lungs, and that the condition above described is not infrequently due to post-mortem changes; and if the bodies of those who have died of cholera be examined immediately after death, the left side of the heart will be found as full of blood as the right side, but as post-mortem rigidity sets in, the blood is forced from the left ventricle into the aorta, and in fact from the large arteries of the body into the capillaries and veins. He has less hesitation in express-

ing an opinion of this kind, because under similar circumstances he was misled into attributing an important place in the pathology of cholera to the shedding of the intestinal epithelium, as observed after death: more recent researches have, however, convinced him that the shedding of the epithelial cells, *en masse*, is also a post-mortem change, which takes place usually about an hour, and a half or two hours after death.

SYMPTOMS.—Asiatic cholera is most deadly at the commencement of an epidemic, and then usually begins without premonitory symptoms. The patient feels well up to within a few hours of the attack, or, it may be, goes to bed and sleeps soundly through the night, and immediately on rising in the morning is seized with violent purging and vomiting. After the first outburst of the disease, as a rule, cholera commences with diarrhoea, the stools being copious and watery, followed by great prostration of strength, with a peculiar feeling of exhaustion at the pit of the stomach, the sick person suffers from nausea, but seldom from actual vomiting or pain at the outset of the attack. If judiciously treated, many patients recover from this, the *first stage* of cholera, but if neglected the tendency of the disease is to grow rapidly worse. The stools become very frequent, and resemble in appearance and consistency the water in which rice has been boiled: these liquid evacuations flow away from the sick person with a sense of relief rather than otherwise; but the patient now commences to vomit, first throwing up the contents of his stomach and subsequently all the water he drinks, mixed with mucus and disintegrated epithelium, the fluid is ejected from his mouth with considerable force, and this adds to the increasing prostration which is one of the most urgent and marked features of the disease. The patient complains of intense thirst, and a burning heat at the pit of his stomach, he suffers also excruciating pain from cramps in the muscles of the extremities, he is terribly restless, and his urgent cry is for water to quench his thirst, and that some one might rub his limbs, and thus relieve the muscular spasm. Although the temperature of the sick person's body falls below the normal standard, he complains of feeling hot, and throws off the bed-clothes in order that he may keep himself cool. The pulse is rapid and very weak, the respirations are hurried, and the patient's voice becomes husky. His countenance is pinched, and the integument of his body feels inelastic and doughy, while the skin of his hands and feet becomes wrinkled and purplish in colour. The duration of this, the *second stage* of cholera, is very uncertain; it may last for two or three hours only, or may continue for twelve or fifteen hours; but so long as the pulse can be felt at the wrist, there are still good hopes of the sick person's recovery. The weaker the pulse becomes, the nearer the patient is to the *third, or collapse-stage* of cholera, from which probably not more than thirty-five per cent. recover. This, however, depends much on the condition of the patient's heart; it is quite possible, although the cases must be rare, that a sudden outpouring of fluid into the intestinal canal has been sufficient to cause syncope and death, among

persons suffering from a weak heart, before the liquid contents of the bowels have had time to be rejected either by the mouth or anus. In the third stage of the disease the vomiting and purging continue, although in a mitigated form; and the skin is covered with a clammy perspiration, especially if the cramps are still severe. We now cease to be able to feel the pulse at the wrist, the lividity of the extremities and surface of the body increases, the patient cannot speak above a low whisper, his breathing is very rapid, his eyeballs are deeply sunk in their sockets, and his features are marvellously changed within a few hours. The urine is suppressed. The temperature of his body may fall as low as 94° Fahr. The patient remains terribly restless, longing only for sleep, and that he may be supplied with water. His intellect is clear, but he seldom expresses any anxiety regarding worldly affairs, although fully conscious of the dangerous condition he is in, sleep, and a plentiful supply of drinking water, are the sole desires of a person passing through the collapse-stage of cholera. This condition seldom lasts for more than twenty-four hours, and reaction either commences within that period, or the patient dies in collapse, or passes on into the *tepid stage*, which in nine-tenths cases out of a hundred ends speedily in death. In the tepid stage of the disease the sick person's body feels cold to the touch, but the temperature, as shown by the thermometer, begins to rise very rapidly, sometimes marking 99° or 100° F. The purging and vomiting cease, and the patient lies in a semi-comatose state, his eyes half open, the ocular conjunctiva being deeply congested, the cornea hazy, and the pupils fixed; the pulse can be felt at the wrist, but the respiration is very hurried, suppression of urine continues, the patient's body is bathed in a cold clammy perspiration, the skin becomes of a dusky red hue, and death too frequently closes the scene within a few hours.

On the other hand, the sick person having been in the collapse-stage of cholera some twenty-four hours (it may be a longer or shorter period), the temperature of his body may begin to rise, gradually creeping up to the normal standard; the respiration diminishes in frequency; the pulse returns, the patient can sleep, and after some thirty-six hours may pass a little urine. In fact, the functions of animal life are slowly restored, and the sick person recovers his health. This desirable result, however, is not infrequently thwarted by various complications which arise during the stage of reaction. Of these complications the following are the most important:—suppression of urine; gastritis and enteritis, pulmonary congestion; meningitis; sloughing of the cornea; abscesses over the body; the formation of coagula in the right side of the heart or pulmonary arteries; hemorrhage from the bowels; and roseola-cholericæ.

DIAGNOSIS.—The question of the diagnosis of Asiatic cholera is discussed in the article on CHOLERIC DIARRHŒA.

PROGNOSIS.—The means of forming a prognosis in cholera will be gathered from the preceding account of the disease. Speaking generally, the prognosis depends chiefly upon the stage of the disease, and upon the time of the epidemic.

that is, according as the patient has been seized at the outbreak, at the height, or towards the end of an epidemic.

TREATMENT.—In the first stage of Asiatic cholera we should endeavour to stop the purging, and without doubt opium is the drug upon which we may with the greatest confidence rely for effecting this purpose. When practising in the endemic area of cholera the writer was in the habit of carrying about pills containing one grain of opium and four of acetate of lead, so that, if called to see a patient suffering from the disease in its early stage, no time was lost in administering one of these pills dissolved in water. The next thing done was to make a large mustard poultice, and apply it over the whole surface of the patient's abdomen. The sick person was ordered to remain in bed, and to be allowed nothing in the shape of food or water; but he might suck as much ice as he felt inclined for.

If, after the first pill, the patient was again purged, a second was given, and a third (but not more) after each loose motion. It often happened that the first or second pill, together with the mustard poultice, ice, and rest, was sufficient to check the progress of the disease, and the patient recovered. Supposing this treatment not to succeed, or that on first seeing the patient it be found that he has passed into the second stage of the disease, we should still prescribe the pill, as above directed, dissolving it in water, because in the solid form it might be rejected entire, and under any circumstances it would take time to be dissolved by the fluid contained in the stomach, the mustard poultice also should be applied, and the sick person kept warm and in bed. Ice is invaluable in this stage of the disease, and unless a person has passed through an attack of cholera, it is impossible to realise the immense relief it affords; it should be given in small lumps, the sick person eating and swallowing as much as he chooses, he will frequently devour a pound or two of ice in the course of an hour, and he cannot take too much of it. In the treatment of cholera there can be no question as to the value of ice. The patient should be prohibited from drinking water or any other fluid beyond that which he gets from the ice. The practitioner must be firm on this point, turning a deaf ear to the entreaties of the sick man or his friends, that he may be permitted to swallow even a small quantity of water, for if they once break through this rule, it will be impossible to limit the amount of liquid the patient will consume. If this treatment does not check the progress of the malady, we may prescribe three grains of acetate of lead and fifteen drops of diluted acetic acid in water every second hour, and fifteen drops of diluted sulphuric acid in water every alternate hour, so that the patient should take a draught, first of one mixture then of the other, every hour. The writer often combines five drops of spirit of camphor with each dose of the medicine, but this drug requires care in its administration, and should seldom be continued beyond five or six doses of from five to ten drops each. Should the vomiting be very severe, in spite of the free administration of ice, a second mustard

poultice should be applied over the abdomen; and medicine must then be omitted for an hour and a half, after which time a scruple of calomel may be sprinkled on the patient's tongue, and he should be made to wash it down with a little iced water. The cramps are best relieved by hand-friction, and if very severe, ease may from time to time be given by allowing the patient to inhale some ether. The writer prefers this practice to administering hydrate of chloral, either by the mouth or by subcutaneous injection. Hot water bottles should be applied to the soles of the patient's feet, and also to his legs and abdomen.

Should the disease have reached the collapse stage there is but little we can do for the patient. Ice must still be given, and, if the purging is frequent, the sulphuric acid draught (but no opium) may be administered every hour, heat and friction may with advantage be applied to the surface of the body; and the patient may now be permitted to drink iced water in moderation, provided it does not increase the vomiting. According to the writer's experience, wine and stimulants, if given by the mouth, do harm in this stage of cholera; but, if the purging has abated, enemas of warm beef-tea and brandy may be administered by the rectum every third hour. When reaction comes on, we must guard against doing too much—it is very rare indeed to see a patient in this condition sink from exhaustion, but probably many lives are lost by endeavours erroneously made, under the idea of keeping up the patient's strength. Iced milk or arrowroot is all that should be allowed to be given by the mouth for some time after reaction has set in; but enemas such as those above-mentioned, administered per rectum every five or six hours, are often beneficial, especially if the stomach remains irritable; and under these circumstances we not unfrequently find that a small quantity of solid food is easily digested, when soup and liquids are rejected. In each case, however, the dictates of common sense and experience must guide the medical practitioner in his treatment of the sick person through the convalescent stage of the disease.

With reference to the treatment of suppression of urine after cholera, we should get the patient to drink about half a pint of water every second hour, so as to add fluid to his blood. Dry cupping over the loins should be employed; and ten drops of the tincture of cantharides in water administered every hour, until a drachm of the drug has been given. It need hardly be remarked that suppression of urine after cholera is a most dangerous complication, and there is very little that can be done to restore the suspended functions of the kidneys.

PREVENTIVE TREATMENT.—Among persons predisposed to its influence, the infecting material of Asiatic cholera will manifest its effects on the system within five days of having been swallowed, but the poison does not always engender symptoms of virulent cholera. Nevertheless, in milder cases of the disease the evacuations passed by the patient may contain the germs of cholera, and these evacuations are therefore capable, under certain circumstances, of developing a deadly type of the malady; consequently, the following remarks are applicable to instances of so-called *cholérine*, as well as

to the severer forms of cholera. If the disease has appeared within a neighbourhood, a searching examination must be made into the condition and sources of the local water-supply, not overlooking that of the milk, which is too often diluted with water before being sold. All surface and doubtful wells (especially those in the proximity of drains and cesspools) should be immediately closed, and it is desirable that the drinking water before being consumed should be carefully filtered. All accumulations of house refuse and filth must be removed; and dirty places, both within and without uncleanly premises, must be freely disinfected and cleansed. There is no necessity when the disease is prevalent for making any alteration in the usual diet; but in times of cholera we cannot too strongly insist on at once checking any tendency to diarrhœa, especially if it be of a watery nature. Many cases of incipient cholera have been prevented from running on into dangerous disease, by the early administration of pills containing four grains of acetate of lead and one of opium, one pill to be taken after each loose motion, to the extent of three pills.

If called to treat a case of Asiatic cholera, care should be taken that the rice-water stools, and the matters vomited, are disinfected by means of bichromate of potash or Mædowall's mixture, which should be poured over the bottom of the vessel into which the evacuations are received from the patient; and directly the dejecta are passed from the sick person, a solution of one part of carbolic acid to twenty of water should be sprinkled over them, and they must be immediately taken from the patient's room, and disposed of as follows.—If the sewage of the locality is conveyed away by means of a constant water supply, the disinfected cholera evacuation should be thrown at once into the sewer. Drains used for a purpose of this kind must, however, be flushed with a mixture containing about an ounce of ferro-sulphate to a pint of water. But if the drainage of the place passes into a cesspool, the disinfected cholera stools should be buried in a deep hole in the ground, removed from wells, and, if possible, from human habitations, it is a dangerous practice, however carefully cholera-stools have been disinfected, to allow them to gain access to a cesspool. The room in which the patient has been treated must be freely disinfected, and his bedding subsequently burnt. If the sick person should die, the corpse is at once to be placed in a coffin containing a mixture of lime, charcoal, and carbolic acid, in fact, the body should immediately be buried in a mixture of this kind, and the coffin with its contents committed to the grave within twenty-four hours of the patient's death.

But after all, as Mr. Simon remarks, infinitely the most important preventive measures to be adopted against cholera are to provide a pure supply of drinking water, good drainage, ventilation, and cleanliness; for these means, if rightly enforced, must prevent the cholera contagion, whether disinfected or not, from acting to any great extent on the population.

The Vienna Cholera Conference has decided that quarantine is inapplicable to the circumstances of cholera; but this subject, together

with the duties incumbent on sanitary and port authorities with reference to the preventive treatment of the disease, hardly falls within the scope of this article. C. MACNAMARA.

CHOLERAIC DIARRHŒA. *Strom.*, Simple Cholera, Sporadic Cholera; *Fr.* *Choléra sporadique*; *Ger.* *sporadische Cholera*.

DEFINITION.—An acute catarrhal affection of the mucous membrane of the stomach and small intestines, attended with vomiting and diarrhœa. The stools consist of a serous fluid, containing a little albumin. The whole system is implicated to a greater or less extent, through the rapid loss of water from the body.

ÆTIOLOGY.—As has already been remarked, it is only of late years that the question has arisen as to whether Asiatic cholera and simple cholera are identical diseases; but it seems probable that any obscurity which may exist on the subject occurs from the impression that similar symptoms are necessarily produced from precisely the same causes. It appears reasonable, however, to believe that, if the infecting matter of Asiatic cholera, when introduced into the intestinal canal, induces changes such as we have described, decomposing animal or vegetable substances, under certain conditions, may excite analogous changes in the mucous membrane of the alimentary canal, the consequence being that in both diseases a drain of serous fluid takes place from the bowels, followed by symptoms of cholera. In the case of Asiatic cholera, however, we believe that the discharges have the power, under favouring conditions, of propagating the disease, whereas the evacuations in simple cholera are in this respect barren. Doubtless climatic and meteorological influences very materially affect the susceptibility of the human subject to disease, and consequently we find that simple cholera, like the malignant form of the malady, is apt to prevail as an epidemic in moist or wet seasons of the year, and especially among people whose bodies are predisposed to pass into a diseased condition, from their having habitually breathed impure air, and consumed unwholesome food and water, or become debilitated from other causes.

In a hot and moist climate like that of lower Bengal, choleraic diarrhœa is an affection which we meet with at all seasons of the year, and it is especially prevalent among infants who are being reared on cow's milk, or on other kinds of food prone to undergo putrefaction. Among the fish-eating Hindus the writer has frequently seen several members of the same family who have been seized with symptoms of simple cholera, attributable to the patients having partaken of fish which was slightly tainted. In fact, according to his experience, there are few more certain sources of this form of cholera than fish which has gone bad; and it is very evident that whatever the deleterious influence may be which food of this description contains, the mere fact of keeping it in boiling water for some time does not destroy its pernicious qualities.

It occasionally happens that cases of choleraic diarrhœa occur among people residing in malarious districts, the diarrhœa taking the place of the cold stage of a fit of ague; patients

under these circumstances have been seized with all the symptoms of severe cholera, but they have, almost invariably, recovered from the attack.

SYMPTOMS.—Choleraic diarrhœa begins suddenly; that is, the patient, whether an infant or an adult, has probably up to the commencement of the attack been in good health; there are in fact seldom any premonitory symptoms. A child may perhaps look somewhat paler than usual, and has a dark ring under his eyes, but beyond this appears to be perfectly well. Shortly after taking food, the infant vomits up a quantity of uncoagulated milk, the evacuation not being curdled like that from an overloaded stomach, the gastric secretion no longer having the power of coagulating the casein of milk. Soon after vomiting, or it may be before, the child commences to pass from the bowels an acid greenish-yellow fluid, containing flakes and often lumps of undigested food. The little patient becomes very thirsty, restless, and is evidently in considerable pain, crying, and drawing his legs up towards the abdomen. If those symptoms continue the evacuations become colourless, resembling in appearance the rice-water stools of Asiatic cholera. The temperature of the body falls, the face becomes of a dusky hue, the features are contracted, and the eyeballs deeply sunk in their sockets; the fontanelles are depressed, the child is evidently terribly prostrated, his pulse can no longer be felt at the wrist, and his crying passes into a weak whimpering, he eagerly drinks water when offered him; and, as the exhaustion increases, convulsions supervene, and the child dies within a few days or even hours. On the other hand, the symptoms may abate at any stage of the disease, and the little patient gradually recovers his health.

In the adult the symptoms induced by choleraic diarrhœa are much the same as those above detailed. There are seldom any premonitory symptoms, and the attack begins with nausea and vomiting, together with a sensation of exhaustion referrible to the pit of the stomach; the vomiting is speedily followed, or it may be preceded, by purging; copious watery discharges are thus passed out of the body, and the larger and more rapid the evacuations, the more they come to resemble the serum of the blood, which, in fact, drains into the intestinal canal, and passes away from the stomach and bowels. The patient naturally complains under the circumstances of intense thirst: he is very restless, and at the commencement of the attack suffers from colicky pains in the abdomen, and subsequently from spasms and cramps which often seize the muscles of the extremities. The pulse becomes small and weak, the respiration is hurried, the voice feeble, and the countenance pale and shrunken. The urine is scanty or suppressed, and the temperature of the body falls one or two degrees below the usual standard. These symptoms, as a rule, gradually subside, the purging and vomiting cease, and the patient falls off to sleep, waking more or less exhausted in proportion to the severity of the attack, but he usually recovers his health rapidly.

DIAGNOSIS.—The question naturally arises, are there any means by which we can distinguish a

case of choleraic diarrhœa from one of Asiatic cholera? and in reply it may be affirmed that there is no characteristic symptom by which these affections can be diagnosed from one another. But, taking all the circumstances of any particular case into consideration, it is difficult, except on paper, to confound the two diseases, for unless a patient has recently imbibed the poison which produces Asiatic cholera, he cannot be suffering from that malady. Should the sick person reside in a neighbourhood affected by Asiatic cholera, we must, in forming an opinion as to the nature of the affection, be guided by the previous history of the case, the nature of the food consumed, and so on, and, above all, by the severity of the symptoms. Choleraic diarrhœa, even in the tropics, rarely passes on within a few hours from the commencement of the attack into collapse, such as is commonly seen in cases of Asiatic cholera; and, in the early stages of the former disease, there is seldom that complete loss of voice and pulse so characteristic of the malignant form of this affection. An experienced medical practitioner, placed at the bedside of a person suffering from Asiatic cholera, even in its earliest stages, feels no doubt whatever as to the nature of the affection, and is at once impressed with the grave responsibility of the charge which rests upon him: his anxiety is infinitely less when he meets with an instance of choleraic diarrhœa, although he is unable to lay down any hard and fast rules by means of which he could define the difference that exists between the symptoms present, and those occurring in a case of Asiatic cholera.

PROGNOSIS.—Although choleraic diarrhœa in its more severe forms resembles mild cases of Asiatic cholera, it is a comparatively harmless disease. Unless among young infants, or old and sickly people, no matter how threatening the symptoms may be, however great the collapse and depression of the patient may seem, a previously healthy adult seldom dies of choleraic diarrhœa.

TREATMENT.—In cases of simple cholera occurring among children, the important point we must enforce in our treatment is that the affected organ shall have rest. In practice, however, it is often difficult to persuade parents and nurses that an infant can exist uninjured for ten or fourteen hours on iced water; nevertheless, we must insist on a plan of this kind being carried out. The little patient will eagerly swallow cold water, either from a bottle or spoon, and the child may be allowed to take as much cold water as he requires, and to suck ice, which may be wrapped up in the corner of a handkerchief and put into his mouth. A poultice made of equal parts of mustard and flour, applied over the abdomen, is often very useful in this form of disease. With reference to drugs, should the treatment above indicated not relieve the symptoms, or should the vomiting be very constant, four grains of calomel may be given, and repeated if necessary in an hour's time; but if the diarrhœa is the more prominent symptom, calomel is not required, but a teaspoonful of castor oil should be administered, and after the bowels have been cleared out, if the serous discharge continues, we should order astringents, in the form of $\frac{1}{2}$ of a grain of acetate of lead every hour,

or $\frac{1}{16}$ of a grain of nitrate of silver, until the purging subsides. Tannic acid, in combination with dilute sulphuric acid and sugar, is frequently a useful combination to administer to children in cases of this description. With reference to opium, much as the writer dislikes prescribing it for infants, it may be necessary in cases of simple cholera, but it should hardly be given in a mixture to be administered from time to time by a nurse; opium under these circumstances can only be admissible when given by the medical attendant, himself, in doses of two or three drops of laudanum in a little weak brandy and water, carefully watching its effects. If the drug causes the child to sleep for a few hours it may act almost like a charm; the infant awakes comparatively well; but if the opium has no such effect, we may be tempted to repeat the dose, but can scarcely give it a third time, at any rate until some hours have elapsed since the administration of the second dose. The symptoms having subsided, the child's diet must be strictly attended to, a good healthy wet-nurse as a rule being an urgent necessity in the case of infants. Lime-water may with advantage be mixed with the child's food.

With reference to the treatment of adults suffering from choleraic diarrhœa, we must bear in mind the fact that, unless among old and debilitated persons, the patient will, as a rule get well without medicine. If therefore called to prescribe for a case of this complaint, we may order fifteen drops of laudanum, or a drachm of the compound tincture of camphor in water, to be taken (supposing the patient is very sick) immediately after vomiting; half the above dose may be given at the expiration of one hour, and again after another hour, unless the symptoms have in the meantime subsided. A large mustard poultice should be applied over the abdomen, and the patient must be confined to bed, and kept on ice and iced water, he should not, however, be permitted to swallow too much liquid. Among old or weakly persons, and also in the case of infants, it is often very necessary to administer brandy and water from time to time, according to the state of the pulse. If the vomiting is severe, a scruple of calomel may be given to an adult, or in the first instance the effervescent mixture with hydrocyanic acid may be employed to allay the sickness; on the other hand, should the serious diarrhœa be excessive, we may with advantage prescribe four grains of the acetate of lead and ten drops of diluted acetic acid every second hour; or pills containing a drop of creasote, a quarter of a grain of nitrate of silver, a grain of camphor, and two grains of Dover's powder, to be repeated after each loose motion. C. MACNAMARA.

CHOLERINE—A term applied to a class of cases which occur during the prevalence of cholera, in which the milder symptoms of the disease are present. It has also been used to designate the poison on which cholera is supposed to depend. See CHOLERA, and CHOLERAIC DIARRHŒA.

CHOLESTEATOMA (χολή, bile; στήν, steth; and όμα, like).—An encysted tumour, consisting chiefly of cholesterine. See CYST.

CHOLESTERINE. See Appendix.

CHORDEE (χορδή, a harpstring).—DEFINITION.—Painful imperfect erection of the penis during gonorrhœa.

ÆTIOLOGY AND PATHOLOGY.—Chordee is most common in the second and third weeks, and rarely attacks the patient after the third week of gonorrhœa. In exceptional cases, on the contrary, chordee, absent in the acute stage, is violently developed after the inflammation has become chronic and very slight. The bulbous part of the urethra is generally intensely inflamed when chordee happens; and, further, chordee is very uncommon when the urethritis is limited to the anterior or posterior portions of the canal.

The mechanism of chordee is imperfectly understood. Two explanations have been put forward:—(a) That the corpus spongiosum surrounding the urethra being affected by inflammation through the effusion of lymph into its substance, proper distension of its spongy tissue and elongation during erection cannot take place. Hence it is drawn tight like a bowstring by the arching of the distended corpora cavernosa. (b) That the inflammatory condition of the mucous membrane and submucous tissue at the bulbous part excites reflex spasm of the muscles surrounding that part of the corpus spongiosum. This prevents distension of the parts compressed, while the corpora cavernosa, being untrammelled, continue to expand in the ordinary manner. The first explanation is insufficient to account for some cases where the inflammatory action is very slight and there is no evidence that lymph has been effused into the erectile tissue; for example, after a plastic operation on the penis. Again, natural erection has been known to take place very shortly after the subsidence of gonorrhœal irritation, and, it is fair to suppose, before effused lymph can have been absorbed. The second explanation is unsatisfactory, because spasm of other muscles of the perineum is often absent. Probably both methods may be active in producing chordee.

The causes of chordee are *indirect* or *direct*. The most common indirect cause is urethritis or urethral congestion. Direct causes are the reflex irritants which usually produce erection during sleep, such as stimulating food and drink, strongly acid urine, great superficial warmth of the body, distended bladder, lascivious dreams, &c.

SYMPTOMS.—The organ grows suddenly turgid and assumes a bowed or crooked form, causing acute pain, which is felt at the part and towards the perineum. In severe cases the strain causes rupture of the mucous membrane and spongy tissue, with hemorrhage. The loss of blood is usually limited to a few drops, and gives relief to the pain. Rarely the hemorrhage is rapid and prolonged.

TREATMENT.—Abstinence from stimulants of all kinds and late suppers; light clothing; and a hard mattress at night are the best means of preventing chordee. Micturition at short intervals during the night must be enjoined. Of medicines the best is a suppository at bed-time of one grain of crude opium in ten grains of cocoa butter. The subcutaneous injection into

the perineum of one-sixth grain of acetate of morphia is also an effectual remedy. Both these applications should be followed by an aperient saline draught the next morning. A drachm of spirit of camphor thrown just before it is swallowed into an ounce of water, and taken on lying down at night is also useful, and it may be repeated once if choreus awaken the patient, but it is a very uncertain remedy. More trustworthy are twenty or twenty-five grains of chloral-hydrate in syrup and water at bed-time, and repeated in four or six hours if needed. Bathing the genitals and perineum with very hot water for ten minutes before going to bed sometimes proves successful. The application of a spiral coil of narrow india-rubber tubing round the penis and scrotum, through which a continuous current of ice-cold water flows, is also an excellent preventive.—To disperse an attack of choreus the best remedies are voiding urine; the application of cold to the perineum by evaporating lotion or by ice; and the upright posture.

BEKKLEY HILL.

CHOREA (*chorea*, a dance).—SYNON.: Choreia Minor; St. Vitus's Dance; Fr. *Danse de St.-Guy*; *la Chorée*; Ger. *Veitstanz*.

DEFINITION.—A disease of the nervous system, characterised by a succession of irregular, clonic, involuntary movements of limited range, occurring in almost all parts of the body.

The distinctive features of the movements are the entire absence of either rhythm or method in their recurrence; that not individual muscles but co-ordinated groups are affected, and not one or more groups only, but almost all the muscles in turn. There is not actual loss of command over the muscles, but voluntary movements are interfered with by superaddition of involuntary movements. As a rule the movements cease during sleep.

ETIOLOGY.—Chorea is a disease of childhood; it is most common between the ages of eight and twelve, very rare before six, and rare after sixteen; it is more than twice as frequent in girls as in boys, especially after the age of nine. It occurs more frequently in families in which nervous diseases are hereditary than in others. It is more common in large towns than in the country; and far more frequent among the poor than among those in comfortable circumstances. Want of proper food, neglect, ill-usage, with the weakness and anemia induced by these means, are very common antecedents. Children well-nourished and with a good colour, exposed to none of these causes, may however suffer. An intimate association between chorea and rheumatism has long been recognised. A large proportion of the children suffering from chorea are found to have had acute or subacute rheumatism, and some of the most terrible cases met with, especially after the age of puberty, are those in which the chorea comes on during or just after acute rheumatism. Whether traceable to rheumatism or not, there is very frequently found in chorea a cardiac murmur, usually mitral systolic, sometimes aortic. This may or may not disappear after recovery. In almost all the fatal cases of chorea which have been examined after death, endocarditis with fibrinous vegetations on the valves has been present. In adults,

pregnancy divides with rheumatism the causation of this affection; recovery generally speedily follows delivery, and can rarely be brought about till this has taken place. Bad habits, and disorders of menstruation, are also said to be capable of inducing chorea. Intestinal worms again have appeared to set up the disease, and instances are on record in which the expulsion of worms has been followed at once by cessation of the movements, but this must be extremely rare. Fright or some powerful emotion is very frequently assigned as a cause, and it is seldom that parents are not prepared with the instance required. But, making allowance for this, and notwithstanding the fact that endocarditis may be present in cases said to have originated in fright, it does not seem possible to exclude fright as a cause of chorea. The influence of imitation is less certain. The disease is said to be far less common in negroes.

ANATOMICAL CHARACTER AND PATHOLOGY.—The study of chorea, as of epilepsy and many other affections of the nervous system, has been hampered by its being regarded as a morbid unity. The view here maintained is that it is a symptom rather than a disease, and that the characteristic movements are in relation not with the nature of the morbid change but with its seat. The seat of the disturbance is the corpus striatum, its character probably different in different cases; but the anatomical condition cannot amount to actual breach of structure, since that is known to give rise to hemiplegia, while it must obviously be of a kind to impair the functional vigour of the ganglia. Chorea, as the writer has said elsewhere, has been called 'insanity of the muscles'—a better phrase would be 'delirium of the sensori-motor ganglia.' In delirium there is loss of control over the mental processes with rapid succession of incoherent and imperfect ideas; in chorea loss of control over the motor apparatus, with movements excessive in point of number and extent, but wanting in vigour and precision.

In some cases of chorea nothing abnormal has been detected after death, but usually the minute methods of investigation now pursued yield positive results. The largest series of examinations published is contained in a communication to the Medico-Chirurgical Society, in the session 1875-6, by Dr. Dickinson. He describes dilatations of the minute arteries as existing throughout the brain and cord, more especially, however, in the corpus striatum and thalamus, with small hæmorrhages; and considers the disease to be due to a widely-spread hyperæmia of the nerve-centres. He did not find capillary embolisms, but does not appear to have drawn out the arterioles to look for them. The appearances he describes are very much those producible by impaction of microscopic particles of fibrin in the minute vessels. Capillary embolisms have been found by Dr. Tuckwell and other observers, predominantly in the central ganglia, but also in the convolutions and cord, accompanied by patches of softening and minute hæmorrhages. In almost all fatal cases of chorea there is endocarditis with deposit of heads of lymph on the mitral or aortic valves or both, whether a murmur has been audible during life or not.

The post-mortem appearances consequently do not indicate any localisation of the morbid change in the central ganglia. But it is to be remembered that the fatal cases are those in which there is not only extreme violence in the choreic movements but usually also delirium and other symptoms. There are in fact multiple symptoms just as there are multiple lesions, and we are called upon to distribute the symptoms and assign them to their respective sources by such knowledge of the functions of the different nerve-centres as physiology affords us. The delirium or comparative dementia is thus attributed to the lesions in the convolutions; the loss of speech to lesions in convolutions or in lower centres, according to its character; the impairment of sensation to lesions in the thalamus; the chorea to lesions in the corpora striata. The grounds upon which this last localisation—that in which we are immediately concerned—is decided, are as follows. We exclude the cerebral hemispheres and cerebellum, rather arbitrarily perhaps, since there is much to be said in favour of their contributing to excite the movement, now especially that convolitional motor areas have been demonstrated by Hitzig and Ferrier. The important point to be made clear, however, is that chorea has not its seat in the cord. The arguments and evidences against this are (1) That *tonic* and not *clonic* spasm is characteristic of persistent spinal irritation; (2) The degree of control over the movements retained by the will; (3) Their increase under emotion; (4) Their cessation during sleep. To those which were originally advanced by Dr Russell Reynolds may be added: (5) The diminished reflex action on tickling; and (6) The phenomena of hemichorea and its relations with hemiplegia. The evidence afforded by hemichorea is so conclusive that other considerations have been merely alluded to. It cannot be supposed, for example, that one lateral half of the entire length of pons, medulla, and cord can be affected without implication of the other half, which would be the case with hemichorea of spinal origin; and still more conclusive is the fact that when in hemichorea there is impairment of sensation it is on the same side with the movements, and not, as in hemiparaplegia (due to division of one half of the cord), on the opposite side to the motor paralysis. The parallelism between hemichorea and hemiplegia is so perfect as to suggest at once that the two affections represent different conditions of the same nerve-centres, and is made more complete by the very discrepancies, as they may at first sight appear, which have been considered to be objections. In hemiplegia there are certain muscles which more or less completely escape paralysis: the *motorius oculorum*, *orbicularis palpebrarum* and other facial muscles, the muscles of the neck, chest, back, and abdomen. In hemichorea the irregular movements cross the median line and invade the opposite side in these same muscles. This has been explained (rightly or wrongly) by the hypothesis that all these muscles acting in compulsory concert with the corresponding (or other) muscles of the opposite side, the nerve-nuclei of the bilaterally associated muscles will be commissurally associated in the cord, so as to become in effect a single nucleus.

and this single nucleus for muscles on each side of the body being connected with both corpora striata is thrown into action by the sound corpus striatum when its fellow of the opposite side is damaged, as in hemiplegia, thus preventing paralysis; and, on the other hand, is reached by the irregular impulses from the corpus striatum affected in hemichorea, thus causing bilateral chorea in the parts enumerated.

In addition to the correspondence between hemichorea and hemiplegia just described, there are transitions from one to the other, and combinations of the two to be mentioned below, under the head of complications. Hemiplegia may be succeeded by hemichorea (the *post-hemiplegic chorea* of various observers); or chorea may deepen into paralysis; or, as in a case reported by the writer, there may be with chorea of the limbs on one side, first chorea, then paralysis (hemiplegiform), and then again chorea of the same side of the face. The conclusion is obvious, that hemiplegia and hemichorea in these cases are indicative of different degrees of damage in the same centre. Hemichorea and hemianæsthesia have been found very constantly associated with structural lesions in the white fibres just outside the posterior extremity of the thalamus, usually involving also the ganglion itself at this part.

The well-known embolic theory of chorea originated by Kirkes, and improved and ably maintained by Dr Hughlings Jackson, at once finds its place here. Capillary embolism is of all others the condition which might be expected to induce the instability without abolition of function which exists in chorea, and in almost all cases a fertile source of fibrinous shreds is present, in the form of vegetations on the valves of the heart; the fact of embolism, again, has repeatedly been demonstrated. While, however, giving to capillary embolism a prominent place among the causes of chorea, it cannot be considered as the only cause. The clinical differences between ordinary chorea and the acute and fatal form are of themselves suggestive of a different pathology; and the speedy recovery after delivery in the chorea of pregnancy, or (as in one or two cases on record) after expulsion of intestinal worms, is inconsistent with the existence of embolism. What the precise anatomical condition is can only be matter of conjecture, but it will be some form of innutrition, irritability, and debility, as Dr C. B. Radcliffe has abundantly demonstrated, going together. Hyperæmia, with capillary blood-stasis, or capillary thrombosis by cohering leucocytes, has been suggested as the cause. Prolonged arterial spasm from persistent reflex irritation, uterine or intestinal, or the more brief contraction of the cerebral vessels from fright, may perhaps lower the functional vigour of the ganglia to the degree required. A very important consideration is the remarkable limitation of chorea to the period of childhood—the period between infancy and puberty. This is a limitation, if not without parallel, certainly unequalled, and it points to a condition of nerve centres in childhood which specially favours the occurrence of the disease. This condition may be said with confidence to be the fact that childhood is the period of special activity of the sensori-motor ganglia.

SYMPTOMS.—In a slight case the patient, usually a child, may be perfectly quiet when lying down, and for a short time even when sitting or standing, if not conscious of being under observation; but when walking or while under examination there will be various fidgety actions, abrupt flexion of the fingers, a sudden pronation of the forearm, or hitching up of one shoulder, or twist of the body, or there is shuffling of a foot on the floor, or again a jerk of the head or twitch of the mouth or eyes. If the patient be told to do anything, the movements will be multiplied and exaggerated in the muscles employed. A small object will be picked up and held, but the hand is brought down upon it hastily and after various irregular excursions. In a more severe case the grimaces, contortions, and jerking succeed each other without intermission. The gait is now very peculiar, being slow, shuffling, and uneven; the steps of irregular length and unequal time; and the line of progress deviating. In the worst forms of this disease every muscle appears to be thrown in turn into violent contraction, the face is distorted this way and that, the eyes roll to and fro, the teeth are snapped or ground together, the whole body writhes, and the limbs are in unceasing motion. It is to be remarked that, even in extreme cases, the movements, violent as they may be, are in some degree circumscribed; the arms, for example, are not thrown up over the head, nor do the legs go to the full extent of their range of motion; the tongue is rarely bitten, though the lips may be. Deglutition is greatly interfered with in a severe attack, and the evacuations may be discharged involuntarily. In the mildest forms, the diaphragm and muscles of the chest and abdomen are affected, causing irregularity in respiration. The action of the heart may also be irregular, but this is probably secondary to the respiratory variations in frequency and depth, and is not attributable to chorea of the heart. There is generally impairment of motor power, and frequently diminution of sensation. This is most readily ascertained in hemichorea, *i.e.* chorea affecting one half of the body only, when the sound side can be employed for comparison, but in the violent forms of the disease, when the skin is gradually worn through by incessant friction, there is often so little complaint of pain that sensibility must, it would seem, be blunted. Reflex sensibility is also, commonly, dull.

It has already been stated that the movements cease during sleep; this is a rule to which exceptions are rare though not unknown, even in mild cases, and especially in hemichorea.

Chorea is usually gradual in access, even in the cases which ultimately become severe; it is very commonly one-sided for a time, and occasionally throughout, when the name hemichorea is given. It is not, however, strictly unilateral in these cases, as the movements transgress the median line and affect the corresponding muscles of both sides of the body at those parts where these are bilaterally associated, and where in hemiplegia there is immunity from the paralysis, as for instance the oculo-motor muscles, the muscles of the neck, chest, and abdomen.

COMPLICATIONS.—The foregoing description applies more or less to all cases of chorea, but there are often additional symptoms, and it will conduce

to clearness if these are considered apart and called complications. Mention has been made of impairment of motor power; at times this amounts to complete paralysis, and the relations and combinations of chorea and paralysis, and especially of hemichorea and hemiplegia, throw much light on the disease. Chorea sometimes succeeds hemiplegia in the paralysed parts, more rarely chorea deepens into paralysis. Cases again occur in which with facial hemiplegia there is chorea of the limbs of the same side. Speech is very commonly more or less affected and occasionally completely lost for a time. The difficulty is usually articulatory, chorea of the muscles of respiration, phonation and articulation interfering with utterance of words; but there is in some cases true aphasia, and when this is so, there is the same tendency to the association of aphasia with right hemichorea as with right hemiplegia. The intellect may suffer in various degrees: the face has often an idiotic expression in chorea, usually no doubt from the muscular contortion or atony, but sometimes truly indicative of temporary imbecility. In the violent and fatal forms of chorea there is almost always delirium. Impairment of sensation is common, and hemianæsthesia is almost always associated with hemichorea.

DURATION, TERMINATIONS AND PROGNOSIS.—The average duration of chorea is about two months; if prolonged beyond three months it may be exceedingly chronic and go on better and worse for one or two years. There is a tendency to spontaneous recovery, but on the other hand relapses are common. Chorea is rarely fatal in children; when it is so the case is usually acute and violent from a very early period of the attack, and it is rare for a case to run the usual course for a time and then take on a very severe character. After puberty and especially when it supervenes on acute rheumatism, it is very dangerous, but less so when associated with menstrual disorders and pregnancy than in youths or men.

DIAGNOSIS.—It is only necessary under this head to warn against the mistake of confounding with the movements of chorea the tremor or jactitation of disseminated sclerosis of the nerve-centres, which, though most common in adults, is not unknown in childhood.

TREATMENT.—In a large proportion of cases of chorea, especially such as come into the hospitals of London, rest and food, with perhaps aperients, are all that are required for recovery. But it can scarcely be denied that medicinal treatment often renders important services, especially in cases of a lingering character. The causation and pathological condition being various, it is to be expected that the remedies required will be different, and the attempt should be made to adapt the treatment to the special features of the case, the basis of all being the endeavour to improve the nutrition of the body generally, and of the nervous system, by good food, rest, and warmth. The food may be supplemented by cod-liver oil, and Dr. C. B. Radcliffe attaches importance to the free administration of wine or other stimulants. Any recognised cause should be removed, such as constipation or worms; irregularities or suspension of the catamenia

should receive attention; when there is pregnancy it may perhaps be necessary to induce premature labour. When the chorea is accompanied by rheumatoid pains and feverishness, iodide of potassium with ammonia may have a remarkably good effect. Iron in some form or other is very generally useful, but especially when the patient is anæmic. Another remedy is sulphate of zinc, given in doses gradually increasing from one or two grains three times a day, to six, eight, or ten, till sickness is induced, when in some cases the disease appears to be cut short. The remedy which in the writer's experience has been found most generally useful is arsenic. Trousseau sometimes gave strychnine in gradually increasing doses till its physiological effects manifested themselves. On the other hand, conium, recommended by Dr. John Harley, has been extensively employed; the only reliable preparation is the juice, which should again be given in gradually increasing doses, beginning with a drachm and going up to one or two ounces if necessary, till its depressing effect on the muscles becomes evident. It has not, in the writer's hands, given satisfactory results; the same may be said of the application of ether-spray along the spine, which has recently been strongly recommended, except in acute cases in which the freezing of the skin here has in two cases been followed at once by sleep, and in a few days by alleviation of the violence of the chorea. Baths, warm and cold, especially shower-baths, spinal doules, spinal ice-bags, gymnastics, musical gymnastics, i.e. movements timed by music, have advocates and may no doubt be useful in suitable cases.

In the terrible cases of acute chorea the great indication is to procure rest for the poor sufferer and keep up the strength. Milk, eggs, beef-teen and other forms of concentrated fluid nourishment, should be given freely, together with wine or brandy. Conium, hyoscyamus, bromide of potassium or ammonium, and chloral, have been tried separately or in combination, with more or less appearance of success, chloroform, again, may be administered; chloral by the mouth or rectum, and hypodermic injection of morphia with free administration of brandy have in the writer's judgment appeared to do much good. It is in these cases that tartar emetic in full doses has been recommended; it is certainly tolerated in an astonishing degree. Restraint of the violent movements is often a great comfort to the patient, the limbs should be carefully bandaged with flannel and bound, the legs together, the arms to the sides, a folded blanket, across the abdomen and hips, keeping down the body. If half-done it only adds to the suffering, but when properly carried out it gives a feeling of relief and favours sleep.

CHOROIDITIS.—Inflammation of the choroid. See EYE, Diseases of.

CHROMIDROSIS (χρῶμα, colour, and ἰδρῶς, sweat), coloured perspiration. See PERSPIRATION, Disorders of.

CHRONIC (χρόνος, time).—This word is applied to a disease when its progress is slow and its duration prolonged. See DISEASE, Duration of.

CHYLOUS URINE.—See CHYLURIA.

CHYLURIA (χυλός, chyle; and οὖρον, urine).—**SYNON.**: Galactaria; Chylous urine; Fr. *Urine laiteuse*; Gor. *Die Chylurie*; *milchsaftiger Harnabgang*.

DEFINITION.—A diseased condition, occurring in tropical and sub-tropical climates, which manifests itself by a milky appearance of the urine, accompanied usually with more or less distinct traces of blood. On standing, the fluid coagulates, so as to present the appearance of size. A microscopic nematoid entozoon (*Filaria sanguinis hominis*) is generally found in the blood and urine of persons affected with the disease.

GENERAL DESCRIPTION.—The affection known as chylous or chylid urine has long remained a puzzle to physicians, not only on account of the very remarkable character assumed by the secretion, but also on account of the very erratic course which the disease runs. Scarcely any two persons affected with this malady give a similar account of its mode of onset, of the duration of the attack, or of the symptoms and seasons of its occurrence. The writer has had the opportunity of studying from thirty to forty cases of the disease in Calcutta, and the variety of symptoms presented, and the numerous causes, of the most opposite character, to which the disease has been attributed, are very perplexing. The histories of the cases published by various observers present a like uncertainty, and Dr William Roberts very aptly describes the course which the disease runs as marked by an irregularity and capriciousness which baffles explanation. It would seem as though the one symptom which may be looked upon as constant is the condition of the urine implied by the designation which was applied to the disorder by Prout.

This symptom, however, although very applicable to the generality of cases met with in India, does not appear to be so generally applicable to the disease as it occurs in Egypt, the Brazils, and the West Indies. In these countries the term *hematuria* is adopted as being a more correct description of the malady, whereas in India the designation 'hematuria,' though generally more or less applicable at some period or other of the disease, is, nevertheless, not so appropriate in the great majority of the cases, and, indeed, in some instances is wholly inappropriate, as occasionally no marked traces of red colouring matter can be detected in the urine from the beginning to the close of the attack. It is of importance that this feature in connection with the disease should be borne in mind, as it may hereafter be found that what at present are generally considered as merely two phases of one malady may each have a distinctive etiology.

HISTORY AND GEOGRAPHICAL DISTRIBUTION.—The phase which chyluria usually presents in India is, in this article, taken as the typical one, and its history may be thus briefly epitomised. To Dr. Vandyke Carter belongs the credit of having observed systematically, and seriously attempted to clear up the pathology of the disease. His researches, published in 1861-62 tended to show that a direct admixture of chyle and urine occurred—a leak from the lymphatic tract into the urinary.¹ In March 1870, when

¹ *Transactions Med. and Phys. Soc. Bombay*, vol. vii. 1861. *Médecine-chir. Trans.*, vol. xlv., 1862.

examining a specimen of milky urine passed by a man under the charge of Dr. R. T. Lyons in Calcutta, the writer found that it contained numerous microscopic nematoid worms in a living condition. These were described and figured in a report published in 1870 by the Indian Government.¹ Under the impression that no nematoid parasites had previously been found in the urine, specimens were forwarded to the late Dr. Parkes, and by him shown to Professor Busk, who suggested that probably they belonged to the Filariæ. Similar entozoa were detected in the urine of chyluria patients in Calcutta by Dr. W. J. Palmer and Dr. Charles in the course of the next few months. Towards the beginning of July 1872 the writer found nine minute nematoid worms in a state of great activity on a slide containing a drop of blood from the finger of a Hindoo. These were identical in character with those above referred to. Unfortunately the man could not be found after the observation had been made, so as to be questioned as to his past history, so that the pathological conditions which might have been associated with this the first recorded instance of the existence of nematoid hæmatozoa in man must continue to remain in obscurity. However, since this period the writer has traced the helminth (named *Filaria sanguinis hominis*) to the blood direct in about fifteen, and to one or other of the various tissues and secretions of the body in about thirty-five individuals. All with the exception of the person just referred to were known to suffer or to have suffered from chyluria or some closely allied pathological condition.² These observations have, moreover, been confirmed by others in numerous instances.

The more recent history of the variety of the disease usually referred to as 'hématurie graisseuse,' 'hæmaturia Braziliensis,' 'hæmaturia Egyptica,' is also associated with an entozoon—or rather with two distinct kinds of entozoa—a fluke and a nematode. The former was discovered in 1851 by Bilharz. His observation was followed up, and now it is estimated that about a third of the inhabitants of Brazil harbour this parasite in their bodies. In 1868 Dr. Otto Wucherer, of Bahia, discovered a microscopic entozoon, which he forwarded to Leuckart to be identified.³ The latter writer suggested that it might be the embryo of some round worm, probably belonging to the strongylidæ. Dr. Jules Crevaux, a French naval surgeon, succeeded in confirming Wucherer's observation by finding (July 27, 1870) similar helminths in the urine of a young creole affected with 'hématurie chylique.'⁴ The next link in the chain appears to have been furnished by Dr. Sansino, who, in January 1874 (having no knowledge of previous observations of a like character), found similar parasites in the blood and in the urine of

a Jew lad at Cairo affected with hæmaturia. In the latter fluid distomata also were found. This observer, however, considers that these parasites, though bearing a very close resemblance, differ in some respects from those found in chyluria, and has accordingly added the word *Egyptica* to the original designation for the purpose of distinguishing it. It is possible that the microscopic nematode which was discovered by Wucherer in Bahia may also be traced to the blood eventually, and that the slight differences in the recorded characters in the worm as found in Egypt and in the Brazils from that found in India may be shown to be sufficient to indicate a specific difference in the parasites, and thus offer a satisfactory explanation of the discrepancies observed in the character of the urinary disorder in the different countries.

In Europe the disease has been investigated by several observers. The cases which have come under their care have occurred with very rare exceptions in persons who have at some time or other resided in countries situated between about 30° north and 30° south latitude. Of the four or five cases which have been recorded as having originally occurred in Europe, one is furnished by Dr. William Roberts, the patient never having been out of Lancashire, and another by Dr. Beale, in a person who had never resided out of Norfolk.⁵

SYMPTOMS.—So far as is at present known, there are no premonitory symptoms of chyluria. Sometimes the only symptom is the milky condition of the urine—a condition which usually comes on very suddenly; generally, however, the patient complains of uneasiness, scarcely amounting to pain, across the loins, along the ureters, over the bladder, or along the course of the urethra—especially towards the perineum in the male. There is generally marked debility, with mental depression. Occasionally chylo-serous discharges take place from various parts of the body—the axilla, the surface of the abdomen, the groin, and especially from the scrotum, in that condition of it which is known as Elephantiasis lymphangectodes (Bristowe), Næroid elephantiasis, or Varix lymphaticus. The disease is also sometimes observed associated with true elephantiasis of the limbs and scrotum. It occurs at all ages, from childhood to extreme old age, and in about equal proportion among the sexes—perhaps more frequently in the female than in the male.

With regard to the *urine*, it presents, as already mentioned, a milky appearance, and frequently emits a strong milky or whey-like odour, which is made more evident by warmth. After standing a short time the fluid coagulates, so as to form a more or less semi-solid mass resembling blanc-mange. In the course of a few hours the clot breaks down, and the urine becomes rapidly de-

⁵ Dr. S. Mackenzie exhibited to the Pathological Society (October 1881) living specimens of filaria from a soldier who had served in India. He noticed the daily periodicity of the filaria, which had previously been determined by Dr. Manson of Amoy, and further showed that the periodicity could be inverted from day to night by changing the habits of the individual.

composed. In some cases the fluid presents a pink colour, from the admixture of blood, but more commonly—at least, in India—the blood, when present, is seen forming a shredily adherent coagulum at the bottom of the vessel. Not unfrequently the flow of urine is suddenly stopped during micturition by the blocking up temporarily of the urethra with one of the clots. Sometimes in India, but apparently almost always in the West Indies South America, and Egypt, the presence of blood in the urine forms, as already mentioned, the most pronounced feature. The specific gravity varies greatly—may range in the same individual from 1007 to over 1020. Shaken up with ether the urine loses its milky aspect; and when nitric acid or heat is applied a precipitate almost invariably results. These characters, and the fact of the coagulability of the fluid, indicate the presence of fat, albumen, and fibrin, all of which are to be considered as abnormal constituents. The proportion, however, in which they exist in different individuals, and even in the same individual at different times, varies greatly. Dr. Beale's analyses show, that though a specimen of urine may contain at one time 1.39 per cent. of fat, another specimen, obtained a few hours later, from the same person, may contain none. In the majority of cases the fatty element is usually scanty in the morning before meals, and so are the other abnormal elements, unless exercise have been taken or the circulation otherwise accelerated. Under the latter circumstances, as Dr. Bence-Jones has shown, the albumen is increased, without, however, a corresponding increase of the fat.¹ It is evident, therefore, that in order to institute a comparison between the character of the urine and the character of the various nutritive fluids for the purpose of ascertaining from which of them the abnormal constituents of the urine are derived, the results of analyses of the latter fluids at different times of the day and at different stages of the disease should be taken. Further, as the nutritive fluids themselves undergo constant changes dependent on the quality of the nourishment supplied and the time which has elapsed since partaking of it, it is equally evident that any single analysis would be insufficient. An attempt has been made to bring together in the following table all of what appeared to be the most trustworthy analyses of these fluids which have been published. In order to simplify the table, only the estimates of the albuminoid and fatty matters have been given, these being the most pronounced of the more readily estimated abnormal constituents in the urine:—

Constituents selected.	URINE in chyluria. [Mean of 15 analyses.]	BLOOD in chyluria. [Hoppe-Seyler.]	BLOOD—Normal human. [Bequerel and Rodier.]	CHYLE [Mean of 6 analyses man, cow, horse, ass, dog, cat.]	LYMPH [Mean of 4 analyses.]
Albuminoids	0.54%	3.35%	7.00%	7.08%	3.96%
Fatty matters.	0.80%	0.67%	0.06%	0.92%	0.56%

¹ *Phil. Trans. of Royal Soc.*, cxl., 1850, p. 651.

A glance at this table reveals the fact that the relative proportion of the albuminoids to the fatty matters in chylous urine does not correspond with the proportion in which they are found in any one of the nutritive fluids of the body. In normal blood, for example, the fatty matter is as 1 to 116 of the albuminoid, whereas in the urine the former exceeds the latter to a very considerable extent. The same discrepancy, but to a less degree, is found to exist when the urine and chyle are compared—the quantity of albumen in the latter being more than seven times greater than that of fat. The proportion of these substances in lymph approaches more closely to what is encountered in the urine—the fat being to the albumen as 1 to 4 very nearly. The specimen of chyluria-blood recently analysed by Hoppe-Seyler¹ approaches very closely to the average composition of human lymph—the fatty matters being as 1 to 5 of the albuminoid, thus differing in this respect very considerably from Dr. Bence-Jones' analyses of similar blood where the quantity of fat given is that of normal blood. On the other hand, the urine of the man from whom this blood was obtained yielded a proportion of fat almost identical with what Hoppe-Seyler obtained in the urine of the person whose blood he examined—the figures given by the former writer being 0.74 and by the latter 0.72 per cent. The composition of the blood in this affection must be regarded as hitherto unsettled. Guibort found in a clot of it almost twice, and Hoppe-Seyler about eleven times as much fat as is found in normal blood; on the other hand, Rayer, Bence-Jones, and Crevaux could detect no change in its composition. It is possible that the discrepancy in the results of these analyses and macroscopic examinations of the blood may be due in part to the particular moment when the blood was abstracted. According to M. Claude Bernard, 'Les urines chyleuses ressemblent au sang d'un animal en digestion, ou plutôt à celui des oies que l'on engraisse.'²

With regard to the *microscopic examination of the blood*, the writer has not observed that the corpuscles or serum presented any abnormality indicative of the presence of fatty matter in any form—the serum has seemed as clear and as free from molecular matter as normal blood. So far as his experience goes, the only feature worthy of special note in connection with microscopic examination of the blood in chyluria, is the presence of the hematozoon already referred to. In searching for it, it will be advisable to abstract by means of a needle a drop of blood from several fingers, and to submit each slide to a thorough examination, which may have to be very prolonged, employing for this purpose a comparatively low power— $\frac{3}{4}$ " or $\frac{1}{2}$ " objective—a higher power being resorted to when the entozoon has been detected. It must not be expected that the blood will present any peculiarity to the naked eye, even though every ounce may contain thousands of these microscopic worms. The accum-

² Quoted by Crevaux, *op. cit.*

pausing wood-cut, traced from a micro-photograph, accurately represents the size and form of the parasite. Its average length is $\frac{1}{16}$ " (= 0.34 mm.); its breadth $\frac{1}{160}$ " (= 0.007 mm.), or about equal to the diameter of a red blood-corpuscle. It is enclosed in a transparent tubular sac, within which it can be seen to alternately contract and elongate itself. This sac is extremely delicate and translucent, and may sometimes, when the worm has shortened itself more than usual, be seen collapsed and folded like a ribbon, and the next moment be instantaneously straightened again, by the extension of the filaria to its ordinary length. After death the worm may occupy either the entire length of the tubular sac, or be so contracted as to leave the tube empty at one or both ends, as may be observed in the wood-cut.¹ The internal organs are not sufficiently differentiated to be recognised with anything like certainty, although when carefully scrutinised from time to time during the twenty-four or forty-eight hours that the parasites may continue to live, something like differentiation of an alimentary canal may be recognised.

graph.)

Microscopical Characters of the Urine.—

The filaria may likewise be detected in the urine. One day it may be readily obtained in the blood but not in the urine, and *vice versa*; but as a rule, the parasite will be found equally readily in both fluids. In making a search in the urine, it is advisable to pick out one of the coagulated shreds generally found in it transfer it to the glass slide by means of a forceps or pipette, and carefully tease the fragment before applying the cover-glass.

The other leading microscopical character of the urine is the minutely molecular matter—fat in an emulsified condition—to which the fluid owes its opaline or milky aspect. There are also numerous white, lymphoid corpuscles, together with red corpuscles, numerous or the reverse according to the degree of sanguinolence of the urine. Casts of the tubular structure of the kidney—indicative of organic disease of these organs—are seldom to be seen; they were absent in all the cases that have come under the writer's observation.

ANATOMICAL CHARACTERS.—The post-mortem examinations of persons who have died whilst affected with chyluria, also testify to the freedom of the kidneys from disease. This was the case in two autopsies conducted recently

by Dr. McConnell in Calcutta. The writer had the opportunity of examining the kidneys of the first case, and of all the organs of the body of the other case, but could find nothing in any of the organs or tissues suggestive of being a cause of the urinary derangement, except the fact that all the vessels—arteries as well as veins—contained the filaria in their minutest ramifications. It may be further mentioned that the entozoon is present in the chylid-lymphous discharges which have already been referred to as sometimes accompanying chyluria. Of this the writer was able to satisfy himself in 1872, and repeatedly on subsequent occasions. In one of the instances the secretion flowed from the inner corner of the eye, several ounces of which escaped daily; the others were cases of elephantiasis lymphangiectodes, or nœvoid elephantiasis of the scrotum. For a summary of what is known of the latter affection, the reader is referred to a carefully-written paper by Dr. Kenneth McLeod.¹

ÆTIOLOGY AND PATHOLOGY.—Having considered in detail what seem to be the leading pathological features of chyluria, a brief reference may be made to the views which at present prevail regarding its ætiology. These may be comprised under three heads—(1) Dr. Vandyke Carter advocates the view that a direct communication exists between the chyle-carrying vessels and the urinary tracts. (2) MM. Claude Bernard and Ch. Robin believe that the condition of the urine is but a symptom of piærrhœmia—fatty blood; the latter condition being but the normal condition of the blood for some time after the partaking of food, aggravated and made permanent by derangement of the digestive organs—notably the liver. One of these distinguished authors (M. Robin) suggests, further, that this derangement is probably induced in the liver and elsewhere by the *filaria sanguinis hominis*.² (3) The third view to be noticed is that advanced by Dr. W. Roberts. This view appears to be based mainly on the history of a very remarkable case, published by him in 1868. It was one in which a coagulable chylid-lymphous discharge escaped from open vesicles which had formed over the surface of the abdomen: the patient's urine was, moreover, chylous for two days. Dr. Roberts suggests that a coagulation somewhat similar to that on the surface of the abdomen existed in the urinary tract, a sort of eczema—probably on the front of the bladder. Post-mortem examination did not however confirm this view, nor could anything be detected in any of the organs suggestive of a cause, but Dr. Roberts infers that this was probably due 'to the fact that in the last few weeks of life the morbid process had retrograded and had consequently left no appreciable marks on the surface of the bladder.' The examination of the skin in the diseased part showed that the *cutis vera* and the subcutaneous tissue were traversed by short channels or lacunæ from the width of a crow-quill to that of a hair. A careful study of this and other cases suggested to Dr. Roberts the view that one, at least, of the forms of chyluria may be due to hypertrophy of the lymphatic channels and subsequent acquisition by them of gland properties.

¹ The microscopical worms detected by the writer (in July 1874) in the blood of dogs in India—presumably the same species as those discovered by MM. Grube and Delafont in France, about 1843—are not enclosed in an envelope of this kind, although in every other way they appear to be identical; and Dr. Sonzogni states that the hæmatosom found in Egypt is also destitute of this enveloping tube, as is likewise the urinary parasite discovered by Wucherer.

² *Indian Medical Gazette*, August 1874.

³ *Léçons sur les humeurs*; 2nd edit. 1874, p. 345.

In the present state of our knowledge, however, it cannot be said that any of these ingenious explanations meet all the objections that might be raised. For example, before the explanation suggested of the direct leakage of the chyle into the urine can be accepted as sufficient, it must be shown that such a leakage is anatomically possible, and, secondly, that the relative proportion of the leading constituents of the two fluids agree more closely than is suggested by the greater number of the analyses hitherto published. M. Robin's view does not suggest any special anatomical difficulty, but it remains to be demonstrated more conclusively than has hitherto been done that the blood in man ever contains a sufficient quantity of fatty matter to produce such extreme milkiness by admixture with the urine as is observed in chyluria. Dr Roberts' theory is certainly not open to these particular objections, as, given a certain agent to start the formation of these glandular tissues, there does not appear to be any special anatomical or physiological difficulty to be got over; but the result of all the autopsies as yet recorded do not warrant the inference of the existence of such pathological conditions. Future observation, however, may show that they really do exist.

Of the etiological significance of the presence of the filaria in the circulation there can, the writer thinks, scarcely be much doubt—more especially when the number of observations recorded within the short period that has elapsed since attention has been drawn to its existence therein, is taken into consideration. These suggest more than a fortuitous connection; indeed it might rather be said that chylous effusions may be considered as symptomatic of the parasitism. Filariae have even been detected shortly before chyluria had manifested itself. Whether they act injuriously by giving rise to rupture of the walls of the delicate channels in which they circulate and thus cause the escape of the different nutritive fluids into the urinary tract; or whether, as M. Robin suggests, they produce derangements of the liver and other organs which give rise to purriæmia (and, probably M. Robin would add, to rupture of the capillaries, so as to permit of the escape of the abnormally fatty blood), it would be premature to express a definite opinion. It is possible that both Carter and Robin may be correct to some extent, for the disease presents many phases; and the writer would suggest further, that it may also be possible that, in addition to giving rise to the escape of fluid in a purely mechanical manner by causing ruptures, local congestions, and so forth, the entozoon may in some way tend to the production of minute secreting structures (analogous to those described by Roberts as having been formed in the subcutaneous tissues) along the urinary tract, or in other situations, which might permit of the filtration of the ordinary nutritive fluids of the body in a more or less modified condition.—Analyses tend to show that the constituents of these fluids do not reach the urine in the proportions in which they are normally found in the body.

It is also possible that chyluria may occasionally occur unassociated with any parasite, but this remains to be demonstrated.

PROGNOSIS.—Persons have been known to suffer off and on from this affection for from one to fifty years. This would suggest that the malady usually runs a chronic course, which as a rule it doubtless does; on the other hand patients apparently in fair health otherwise have been known to die very unexpectedly from no recognised acute disorder. With regard to the prospect of a cure a very guarded opinion should be given, as the probability is that the complaint will return again and again so long as life lasts—even when the disease commences at a very early age, and often after a complete change of climate and avocation.

TREATMENT.—This has proved extremely unsatisfactory in almost all the cases recorded; in fact it cannot be distinctly stated that the course of the disease has been materially modified, much less cured, by any known remedy. Iodide of potassium has been tried in large doses, and in some cases appears to have been beneficial; in others the tincture of the perchloride of iron has seemed to be more successful. A decoction of the bark of *Rhizophora racemosa* (mangrove) has a reputation in Guiana, just as a decoction of the seed of *Nigella sativa* (used also as a condiment in curries) has in India. The latter remedy has, however, been known to be powerless in mitigating the malady even in cases where on former occasions it had been resorted to with apparent success. Perhaps the most satisfactory results which have been published are those which have followed the administration of large doses of gallic acid—one or two drachms a day. See *FILARIA SANGUINIS-HOMINIS*. TIMOTHY LEWIS.

CICATRIZATION (*cicatrix*, a scar) is the process by which solutions of continuity in an organ or tissue are repaired. These solutions of continuity may be due to injury, ulceration, extravasation, or the effusion of inflammatory products. The result of the process is the formation of a cicatrix or scar.

PATHOLOGY.—Cicatrization, as it occurs in superficial parts in surgical practice, may be selected as affording a typical illustration of the process. It is most frequently and easily observed, and it corresponds to what is met with in deeper tissues.

Repair may take place either with or without the occurrence of granulation, and the process of granulation may or may not be accompanied by suppuration: the existence both of granulation and of suppuration depending on the degree of abnormal stimulation to which the injured tissues are subjected.

In an incised wound favourably circumstanced as to vascularity of tissue, absence of tension, and apposition of edges, epidermic continuity may be re-established in thirty-six to seventy-two hours. The lips of such a wound are temporarily united by a thin layer of lymph and white corpuscles of the blood, and perhaps soon afterwards by cells proliferated from connective-tissue corpuscles. These cells become spindle-shaped, and are ultimately converted into ordinary connective-tissue corpuscles, whilst others from the neighbouring capillaries re-establish the circulation throughout the new tissue. Coincidentally with these changes the surface becomes covered with epidermic scales.

The resulting scar at first appears as a red line, which subsequently becomes white from the disappearance of many of its blood-vessels.

When an open wound heals by scabbing, the epidermis spreads over the tissues without the intervention of the process of granulation, owing to the protection afforded them by the crust of blood and lymph which has formed upon the wound.

Recent antiseptic surgery has shown that even large hollow wounds filled with blood-clot, such as are caused, say, by operation for ununited fracture of the femur, may cicatrize completely without suppuration or granulation, if protected from the stimulation of the antiseptic used. In these cases the white corpuscles of the clot become organized directly into fibro-plastic cells and connective-tissue corpuscles, and the new epidermis will probably be formed beneath a thin upper layer of the clot.

If a recent wound, too large for scabbing, be simply left exposed to the air or treated with water dressing, or with an ordinary antiseptic, there will be a discharge at first of serum tinged with blood, then of pus serum, and latterly of cloudy yellowish serum, replaced in about three days by fully-formed pus. By this time the wound will be studded over with little bright red elevations, termed granulations, which ultimately cover the whole surface. Granulation-tissue consists of nucleated cells, amongst which pass vascular loops with thin walls. After an interval the edges of the skin are seen to be on a level with the granulating surface, and as it were continuous with it. Perhaps already the wound is much smaller, owing to the shrinking of the granulations as their cells assume the spindle-cell type. Then, extending from the cutaneous margin there may be observed a narrow red line, brighter than the rest of the granulating surface, owing to the presence of a layer of transparent epidermis. Next day this zone will be bluish, owing to the growing opacity of the epidermic cells, and there will be a new red line of newest epithelium. A day later the outer layer will have become so opaque as to be whitish, and the second to be bluish; and there will again be a fresh inner red line, which will gradually advance until the scar is complete. The new epidermis quickly separates into a horny and a mucous layer.

The healing of an evacuated abscess-cavity depends partly upon the contraction and partly upon the confluence of the granulations of which its pyogenic membrane consists.

Many cases of disease of joints (caries, &c.), and the behaviour of abscesses treated antiseptically and with adequate drainage, may be referred to as instances of the existence of non-suppurating granulations. JOHN BISHOP.

CINCHONISM.—A condition induced by the administration of quinine, the chief active principle of cinchona. See QUININISM.

OINOCLISIS (κίνησις, I move).—This word signifies agitation or motion, and was formerly applied to involuntary winking or movements of the eyelids; and also to the movements of the chest in dyspnea.

CIRCULATION, Disorders of.—Abnor-

mal excess and deficiency of blood are known as *Hyperemia* and *Anemia* respectively. Each of these may be *general* or *local*.

1. Hyperemia.—*General* hyperemia signifies excess of blood in the body, and is also called *plethora*. *Local* hyperemia means excess of blood in a part. Such excess may be caused either by superabundant supply, or by deficient removal of blood through the agency of the blood-vessels. Dilatation of the arteries, however produced, causes more copious afflux of blood, which fills the capillaries and veins in a corresponding degree, so that there is excess of blood in all the vessels of the part. This condition is called *arterial* or *active hyperemia*, *active congestion*, or *determination of blood*. If, on the other hand, blood is imperfectly removed by the veins, these vessels, as well as the capillaries, become gorged, and the condition called *venous* or *passive hyperemia*, or *venous congestion*, results. There cannot be *capillary hyperemia*, except as the result of one of these conditions.

A. Arterial or Active Hyperemia.—An excessive amount of blood can be conveyed by the arteries only under two conditions:—(1) Enlargement of these vessels by relaxation of their muscular walls; (2) Increased pressure within them, from obstruction of collateral channels with which they communicate, *i.e.* collateral hyperemia.

(1) Relaxation of the muscular walls may be caused *directly* by violence or by warmth, as is illustrated in the redness of the skin produced by a blow, by heat, or by the reaction after intense cold. Sudden withdrawal of pressure has the same effect, as is sometimes seen on evacuating a hydrocele or fluid-collection in a serous cavity. Dry-cupping produces similar but more complex results, the veins being acted upon as much as the arteries. Relaxation of the muscle-fibres is produced also *indirectly* through the vaso-motor nerves. If these are paralysed, relaxation of the fibres occurs, and the arteries dilate. Experimental section of the cervical sympathetic in animals shows this most clearly; but the same result follows less constantly if other nerves containing vaso-motor fibres are divided or injured, such as the mixed nerves of the limbs, or branches of the trigeminus. Wounds of the brachial plexus have been found to cause hyperemia of the fingers (*glossy fingers* of Paget). When the section is complete, hyperemia is only transitory, and is soon followed by a return to the normal condition, or even by undue anemia, which is permanent. In irritative lesions, on the other hand, such as gunshot wounds, hyperemia continues as long as the irritation. In such cases it is possible that the lesion is not paralytic, but depends upon stimulation of the actively-dilating vaso-motor fibres which physiologists have now shown to exist in many parts of the body, since stimulation of these produces the same result as paralysis of the inhibitory fibres. Hyperemia often accompanies neuralgia, both depending upon some morbid condition of the nerve. The starting point of the neurosis in all these cases may be, and often is, in the central nervous system, and hence chronic diseases of the spinal cord or brain are often accompanied by general

paralytic hyperæmia—that is, flushing, or by congestion of special parts. The same result may come from reflex nervous action, set up by disturbances of the digestive organs, the organs of generation, or of other parts.

(2) Collateral hyperæmia is a consequence of the rise of pressure produced by the blocking-up of arterial channels in the adjoining parts. It is usually effected by the enlargement of existing vessels, and the conversion of small, almost capillary, vessels into pulsating arteries. It occurs not only in the familiar instances of surgical ligature, and the sudden blocking of an artery by a plug (see EMBOLISM); but in the gradual obstruction which accompanies atrophic and sclerotic processes. When the chief arterial channels to an organ become obstructed, its peripheral parts are very liable to become hyperæmic, a principle which when applied to such cases as cirrhosis of the liver, granular kidney, and sclerosis of the brain, will be found fruitful in practical deductions.

SIGNS AND RESULTS.—The colour of parts in a state of active hyperæmia is, during life, bright red, the arteries, large and small, being visibly injected, while the capillaries, filled with arterial blood, produce a diffuse red colour. In experimental hyperæmia the blood may remain bright red even in the veins. The temperature of external parts becomes elevated, though not above that of internal parts. Sometimes there is obvious pulsation or throbbing. There may be swelling, which is due to simple enlargement of the vessels, not to exudation of fluid, since this does not occur from arterial hyperæmia alone. The nerves, both those of common sensation and those of special sense, are more excitable than they are normally. There is usually a subjective sensation of warmth, and there may be pain or itching.

Arterial hyperæmia may last for a long time without producing any change whatever in the part affected, but may, under conditions little understood, give rise to hypertrophy, which sometimes, though rarely, results from section of the cervical sympathetic. Transitory but repeated hyperæmic conditions more regularly produce this result, as is seen in hypertrophy from pressure; in thickening of the skull from excessive exposure of the head to the sun; in hypertrophy of the skin and its glands from frequently recurring hyperæmia of the face (*acne rosacea*). This kind of hyperæmia constantly precedes, but can hardly be said to produce, inflammation. It does, however, render the tissues more vulnerable, bringing them into a condition in which a slight cause will set up inflammation. Unless the vessels are unsound, simple arterial hyperæmia does not lead to hæmorrhage.

B. Passive Hyperæmia or Venous Congestion.—This may be due to—(1) Feeble circulation; or (2) Obstruction in the veins.

(1) Blood may be imperfectly removed from a part, owing to the imperfect action of the forces which normally maintain the flow of blood in the veins. These are, besides the action of the heart, the pressure of muscles (combined with the arrangement of the valves in the veins), and the movement of the thorax in inspiration. If these are deficient, the venous current will be

everywhere delayed, but notably in those parts where it has to overcome the action of gravity. In the erect posture this will be the case in the lower limbs, and hence venous congestion is common in the legs, ankles, and feet. In decumbent patients, for analogous reasons, the nates, sacrum, shoulder-blades, and the bases of the lungs behind become the seat of what is called *hypostatic congestion*. Very general obstruction, such as results from imperfection of the heart itself, may lead to the condition called cyanosis, which is essentially venous congestion, and to similar congestion of the lungs, liver, kidneys, and other internal organs, with very serious results.

(2) Obstruction of the veins is rarely produced by a morbid condition of the walls of these vessels, but may result from coagulation of blood within them. Another cause is external pressure, such as that of tumours, of the gravid uterus, or of the intestinal contents, as in the case of the hæmorrhoidal veins. Finally, indurative changes in the solid viscera lead to venous obstruction, as is seen in cirrhosis of the liver, which produces congestion of the whole portal system.

SIGNS AND RESULTS.—The colour of parts in a state of passive hyperæmia is bluish rather than red, the veins, large and small, being injected with venous blood, and the capillaries, in which the blood is also venous, producing a uniform purple colour. If the congestion is extreme, collateral venous channels are likely to be established, which are sometimes the only evident sign of internal venous obstruction. The surface is usually cooler rather than hotter when compared with corresponding parts of the body; and there is no unusual nervous sensibility or sense of throbbing. Swelling very frequently occurs, and depends on actual serous effusion from the vessels, so that the parts are often anasarcaous, pitting on pressure; while in cavities there is an accumulation of fluid.

Venous congestion produces more important and permanent results than arterial. In experimental venous obstruction, besides engorgement of the vessels, two nearly constant phenomena are seen—copious transudation of serum, and migration of a number of red blood-disks through the walls of the capillaries and smaller veins. Few or no white corpuscles emigrate, and the arterial circulation is unaltered. The absence or occurrence of dropsy depends upon the adequacy or inadequacy of the lymphatics to carry off the superfluous serum. In ordinary pathological venous congestion all these changes are seen to some extent; extravasation of red blood-disks being shown by the pigmentation of parts in chronic congestion, though this is not evident in the acute condition. Chronic venous congestion increases the hardness and density of organs, a change which may, in the first instance, result from simple œdema, but in the end is due to fibroid change (see DENSENATIONS). Such organs are at first enlarged, but ultimately diminish in size, and suffer fatty atrophy, not only through the general law of fibroid change, but because venous blood is inadequate to the proper nutrition of tissues. These changes are seen in the liver and kidneys in cases of obstructive heart-disease. External parts, as the skin of the lower part of the leg, show by a tendency

to ulceration that they are imperfectly nourished, and are also liable to become inflamed from slight causes (*varicose eczema*).

POST-MORTEM CHANGES.—The appearance of hyperæmic parts after death is not necessarily the same as during life. The colour of the blood does not enable us to say whether the hyperæmia was arterial or venous. All blood contained in the body after death, excluded from the air, is dark or venous, but becomes florid when exposed to the air, unless it have previously undergone some *post-mortem* change, or some morbid alteration during life. This change may be watched in the lungs when the chest is opened, especially in the case of children whose lungs have little local colour. The only important point after death is the fullness of the three kinds of vessels. Arteries are usually empty, unless diseased; the larger veins almost always full. If the smaller veins and arteries are conspicuously and brightly injected, the part may be described simply as congested, a uniform colour indicates fullness of the capillaries, which may be confirmed by the microscope. Uncomplicated arterial hyperæmia leaves no trace after death; the appearance of it is produced by inflammation. Simple venous hyperæmia can only be recognised as such after death by comparison, that is, with the same part under normal conditions. Chronic venous congestion is indicated by many of the same characters as during life. Care should be taken not to mistake for arterial hyperæmia mere staining with blood-pigment of the walls of the vessels; nor for venous congestion mere *post-mortem* hypostasis, or the settling down of the blood, if fluid, after death.

II. Anæmia.—General anæmia is a morbid condition in which there is a deficiency of blood, or, more correctly, a deficiency of the red corpuscles of the blood, throughout the whole body. It is also called *oligæmia*, or *oligocythæmia* (see *ANÆMIA*). Local anæmia, with which we are here concerned, signifies deficiency of blood in a part. It may be complete or partial. Complete local anæmia can only occur when the blood-supply of a part is totally cut off by obstruction of its arteries. The conditions and consequences of such obstruction are discussed elsewhere (see *EMBOLISM*.) Partial anæmia or *ischæmia* may be produced by direct pressure, or else by arterial obstruction, permanent or transitory. Permanent anæmia of many parts results from gradual obstruction of arteries by atheromatous change, or, still more strikingly, by a form of endarteritis (*endarteritis obliterans*) attributed to syphilis; or, again, from deposition of fibrin on the diseased vascular wall. Temporary anæmia results from spasmodic contraction of the annular fibre-cells in the muscular coat of the artery. Such a contraction may be produced experimentally by direct electrical stimulation, or by stimulation of the sympathetic branches distributed to the vessel; and in pathological conditions we find such contraction occurring in consequence of some derangement of the nerve-centres, or from reflex irritation, or even, as it would seem, idiopathically. Neuralgia and migraine are often accompanied or caused by spasm of the arteries, and epilepsy has, with less certainty, been attributed to the same cause. In these cases it is possible, as is

held by some authorities, that anæmia of the nerve-tissue is the cause of the disturbed innervation. Hysterical blindness, and probably other hysterical affections, may be explained in the same way.

SIGNS AND RESULTS.—An anæmic part is pale, its temperature in the case of external parts is diminished, and there is weakened or arrested arterial pulsation. A permanent condition of anæmia, even if only partial, produces degeneration, ending in atrophy of the affected part. The wasting of the skin, and possibly that of the kidneys in old age, is due to this cause. Transitory anæmia causes necessarily a cessation of functional activity in the part, as is obvious in the nerve-centres and the muscles but does not, so far as we know, produce any permanent change. Compression or obstruction of the abdominal aorta produces symptoms of temporary paraplegia. J. F. PAYNE.

CIRCULATION, Diseases of Organs of. The organs of circulation comprehend the heart, the arteries, the veins, and the intervening capillaries. The diseases affecting each of these structures will be found described under their respective headings. It has, however, been thought desirable to give in this place a general sketch of the different ways in which the intimate relations that exist between the parts of the circulatory apparatus may be disturbed by disease. While the heart, the arteries, the veins, and the capillaries have each special diseases, related to their differences of structure and of function, the effect of such diseases is rarely or never purely local. The other parts of the circulation on either side of the lesion and the regions to which the vessels are distributed suffer more or less from the local disease. This is true whether the disease be structural or only functional; and whether, in the latter case, the nervous system or the blood be the primary seat of the disorder. Viewed thus, the subject will be best considered under three heads:—1. The *structural changes* of the several organs of circulation, and the diseases and disorders to which they give rise in other parts of the system whether general or local. 2. The *functional disorders* of the organs of circulation due to nervous disturbance, both local and general. 3. The *functional disorders* of the circulation due to changes in the blood. We shall discuss these divisions in the order in which they have been named.

(A)—**STRUCTURAL CHANGES IN THE ORGANS OF CIRCULATION.**—The heart is liable to organic disease either in its propelling muscular walls, its regulating valves, or its controlling nervous system; and it will be found that diseases of each of these parts of the cardiac apparatus affect respectively its several functions. Thus disease of the walls of the heart affects the force or pressure; valvular disease primarily disturbs the distribution or quantity of blood in the several parts of the circulation, while nervous disorder especially interferes with the rate and regularity of its movements. Diseases of the arteries interfere with the quantity of blood transmitted through them, and produce secondary disturbances of distribution or of pressure. When the capillary walls are degenerated or ruptured, or when their canals

are blocked as a result of embolism or thrombosis in arteries or veins, nutrition is disturbed in various ways. Lastly, the *veins* may be the seat of a variety of lesions, which prevent the return of blood, and lead to hemorrhage or to dropsy. We shall consider the diseases that have been above indicated from a common point of view, viz. their effects upon the circulation.

1. The *pressure* of blood within the circulation may be either increased, diminished, or irregularly distributed. The most marked instance of *increased* pressure is seen in simple hypertrophy of the left ventricle without valvular disease, especially if the hypertrophy be associated with increased peripheral resistance, as observed in chronic Bright's disease. The effects of increased pressure on the *heart* are cardiac enlargement with its consequences, and valvular disease; in the *arteries*, they are fulness, stontation, thickening, and atheroma with its results. The *pulse* is strong and full, and may possess the various characters of the vessel-wall just enumerated. The *capillaries* are over-distended, and may be ruptured, hemorrhage being the result. The functions of the several organs are, under favourable circumstances, more active, and the *venous* circulation is more free.

Diminished pressure of the circulation is more common, and is seen in dilatation with thinning of the cardiac walls, in atrophy, in fatty degeneration, and in fibroid hypertrophy or degeneration. The effects of diminished pressure within the circulation generally are the reverse of those of increased pressure. The *arteries* are comparatively empty and small, and the pulse is weak, small, and often irregular. The *capillaries* are insufficiently supplied with blood; the visible surfaces are anemic, or passively congested; and the various functions are feebly discharged. The backward pressure within the *veins* is, on the contrary, increased; the blood tends to accumulate within them, the walls are dilated; the valves are disorganised, and passive congestion, thrombosis, dropsy, and chronic inflammation are frequent results.

2. The *Quantity of blood distributed*.—What has just been said concerning the pressure of the blood applies, in a great measure, to the quantity distributed through the circulatory system. In hypertrophy of the heart, a larger amount of blood passes through it in a given time, and the arteries and pulse are full, while in atrophy and dilatation the quantity is less, and the pulse is empty and contracted.

3. The most frequent disturbance observed is *irregularity of distribution*. This condition generally affects the pressure and quantity together, but may affect one more than the other. Irregular distribution of blood and of pressure is most markedly present in valvular imperfection, and especially in aortic and mitral regurgitation. It is also seen in obstruction and other allied conditions of the arteries, especially of the aorta. In the parts of the circulation and in the organs situated behind the seat of disease, irregularity of distribution of blood and of pressure is manifested in the form of dilatation, such as enlargement and engorgement of the heart, of congestion and associated changes in the lungs and abdominal viscera, of hemor-

rhage, and of various exudations and effusions whether as oedema, dropsy, or catarrh. On the other hand, the portions of the circulatory apparatus beyond the seat of disease are under-filled and undersized; the organs are deprived of their sufficient supply of blood; and anæmia, with its further consequences, is the result.

4. *Frequency and Rhythm*.—Among the most common forms of cardiac disturbance are alteration of frequency and irregularity of rhythm. Alteration in frequency is generally in the direction of increase; but unnatural slowing may also occur as a symptom of fatty degeneration and other morbid conditions. The essential causes of modifications in the rate of the heart's action are very complex and obscure, for the muscular tissue, the intrinsic nervous apparatus, and the extra-cardiac nerves and centre in the medulla oblongata, may, in different instances, be all more or less concerned. As a rule, increased frequency is associated with, and proportionate to, weakness of ventricular contraction. Unnatural slowing is believed to be generally nervous in its origin, but it may sometimes be due to inertness of the muscular substance from fatty degeneration of the walls of the heart. The remarks that have just been made respecting frequency apply equally to disturbance of rhythm and irregularity of contraction. Frequency and irregularity of pulse in organic disease of the heart are generally indications of serious cardiac weakness, and are often found in the later stages of heart-disease, whether its original seat has been valvular or purietal.

(B) *FUNCTIONAL NERVOUS DISORDERS OF THE CIRCULATION*.—When the distribution and functions of the nervous structures associated with the organs of circulation are considered, the variety and complexity of the disorders of the heart and vessels due to nervous influences will be readily appreciated.

Through the medium of the nervous system, the action of the heart is affected by every sensory impression received by the brain; specially by influences proceeding from the following parts:—the respiratory centre, the respiratory organs, the blood-vessels, the abdominal viscera, the surface of the body, and the cerebrum itself with the organs of sense. Many of the disturbances of the circulation with which the reader is familiar in diseases of the *lungs* are occasioned through nervous channels, especially such respiratory diseases as are attended with imperfect oxygenation of the blood. In the *blood-vessels*, the most marked example of nervous association between them and the heart is afforded by the relaxation of the arteries in cardiac over-distension and embarrassment through the operation of the depressor nerve, which, passing from the heart to the vaso-motor centre in the medulla, inhibits or controls the constricting influences constantly exerted by this centre on the walls of the vessels, and thus effects the relaxation of these vessels and 'depresses' the circulation or lowers the blood-pressure. Cardiac disturbances referable to *abdominal* causes is so familiar that it needs scarcely to be mentioned; and such disturbances, though frequently direct, is more frequently indirect, or reflex through the nervous centres. The

condition of the blood-vessels within the abdomen has the greatest influence on the heart and circulation generally, as may be seen in cases of shock, injury, and inflammation of the peritoneum and great viscera. The *surface* of the body, as the seat of impressions of touch, of temperature, and of common sensibility, may prove to be the source of cardio-vascular nervous disturbance. It is through impressions on the nerves of the surface that the circulation may be disturbed until seriously embarrassed, and even paralyzed, as in shock, exposure to cold, &c.; or, on the other hand, roused to activity, by blistering, flagellation, douching, &c. Lastly, the more extreme and frequent, as well as the more irregular and varied nervous disturbances of the circulatory organs are due to conditions of the *brain*. The most common of all forms of circulatory disturbance is seen in emotional excitement, as palpitation, with vascular throbbing, and as in blushing or in pallor.

The general phenomena of functional disorders of the circulation due to nervous disturbance are—(1) Alteration in the force, frequency, and rhythm of the cardiac movements; and (2) Disturbances of sensibility referable to the condition of the nerves, to distension of the cavities, and to irregular muscular contraction. In certain cases the cardio-vascular disorder may be extensive, complex, and serious, and may involve the neighbouring nerves, as is seen in angina pectoris. The remote effects of these attacks of functional failure are fully described elsewhere. See HEART, Functional Disorders of. Other disorders of a complex character occur such as Graves's disease, which is probably referable to a nervous origin.

(C.) FUNCTIONAL DISORDERS OF THE CIRCULATION, DEPENDING ON THE CONDITION OF THE BLOOD.—The blood is so essentially associated with the organs of circulation, that any alteration either in its quantity or in its composition speedily manifests itself in disorders of the heart or vessels. Besides the effect on the general intra-vascular pressure that follows directly any change in the blood, there are two ways in which any morbid state of this fluid reacts upon the circulation—namely, first, by affecting the nutrition of the cardiac and vascular walls; and, secondly, through the agency of the nervous centres. Thus, when the *amount* of blood is below the normal, not only is the circulation comparatively depressed, but the myocardium is ill-nourished and feeble, the tone of the vessels is low, and the excitability of the nervous centres, which directly or indirectly control the heart, is greatly increased. The opposite condition—of plethora, high blood-pressure, enlarged and powerful heart, and energetic nervous system cannot, within definite limits, be considered morbid, but rather an evidence of too robust health. The most frequent changes in the *quality* of the blood are those which are associated with anemia, as first described. The next most important group of cases is that in which the blood contains some poison, whether generated within the body or introduced from without. The disturbances of the circulation by poisons of all kinds are very numerous and complex. When the poisoning of the blood is

of long duration, and moderate in degree, chronic disease may be set up throughout the organs of circulation; and this is probably the mode of origin of the cardio-vascular disease so often found accompanying chronic Bright's disease.

R. QUAIN, M.D.

CIRRHOSIS (*κίρρῃς*, yellow).—SYNON.: Sclerosis; Fibroid Substitution; Fibroid Degeneration; Chronic Interstitial Inflammation; Fr. *Cirrhose*; Ger. *Cirrhose*.

The term cirrhosis, which was originally invented to describe a particular state of the liver has now acquired a more extended meaning, and is applied to similar morbid processes affecting other organs, though the name itself, derived as it is from the yellow colour of the liver in this disease, ceases to be properly applicable. Cirrhosis may be regarded as a chronic non-suppurative inflammation affecting the interstitial, connective, and supporting tissues of the different organs, and not those by which the proper physiological function is performed. The process begins, after a more or less protracted hyperemia, by the appearance in the interstitial tissues, between the proper functional elements, of small lymphoid corpuscles or leucocytes, which are arranged in lines or tracts interpenetrating the affected organ. These corpuscles crowd the tunica adventitia of the small vessels, the lymph-spaces, and the cavities in which the connective-tissue corpuscles lie; and when present in considerable amount appear to the naked eye as narrow lines of a slightly translucent greyish material. This condition was formerly termed cellular hyperplasia of the connective tissue, and the corpuscles themselves were supposed to originate from proliferation of the connective-tissue corpuscles. More recent researches have, however, shown that in inflammation the connective-tissue corpuscles remain quite passive and take no part in the formation of new cells. The early stage of cirrhosis is therefore more correctly described as cellular infiltration of the connective tissue. The cells themselves are white blood globules, which have emigrated from the vessels, and their descendants. The amount of this cellular exudation varies very much in different organs in the different forms of the disease. In many cases of cirrhosis of the liver, and in the fibroid induration of the left ventricle of the heart, and of the pylorus, it is very considerable, and causes much increase in the bulk of the affected organ. In other instances, as in some forms of granular kidney, it may be very small. Many pathologists consequently regard the process in these cases as essentially one of atrophy of the true physiological tissue, and the indurated fibrous tissue which results as consisting of the withered remains of the vessels ducts, &c. of the organ.

The later stages of the process consist in the conversion of these tracts, which may be looked upon as closely analogous to ordinary granulation-tissue, into fibrous tissue. A more or less fibrillated intercellular substance appears; the corpuscles diminish in number; the remaining ones become in part elongated and oar-shaped, and some may pass into true spindle-cells, or

become stellate: in cirrhosis of the lung tracts of true spindle-cell tissue are often met with. In the liver, where much of this new tissue is often formed, numerous blood-vessels become developed in it: they are devoid of distinct walls and consist merely of channels lined by endothelium. The fibrous tissue which is the final result of the whole process, closely resembles ordinary cicatricial tissue; it is usually tough, dense, and imperfectly fibrillated, with a strong tendency to contract. Sometimes, especially in the suprarenal capsules, and less frequently in the liver, portions of it consist of a reticulated connective tissue.

The effect of this series of changes on the proper physiological tissue of the organ is to cause its atrophy. This is partly due to the direct pressure of the new growth, when it is formed in large quantities, but chiefly to the constriction of the contracting fibrous tissue and the consequent obliteration of the blood-vessels; for even where, as in the liver, new vessels are developed, the original vessels of the organ become obliterated. The atrophy of the proper tissue of the organs appears to take place by a gradual process of granular and fatty degeneration followed by absorption. Sometimes, particularly in the lungs and suprarenal capsules, this change is less gradual, and portions of the original tissue together with the new growth lose their vitality *en masse*, pass at once into a state of fatty degeneration, and ultimately become caseous and even calcareous, giving rise to the formation of opaque yellow nodules surrounded by the semi-translucent grey fibrous tracts. In these cases it becomes difficult to draw a strict line of demarcation between cirrhosis and true tuberculosis, and the difficulty is rendered greater from the fact that chronic tuberculosis in itself sets up the cirrhotic process. In the lung the caseous transformation is no doubt most commonly caused by the filling up of the air-vesicles with large epithelioid catarrhal cells coincidently with the cirrhotic change in the walls of the vessels. These catarrhal cells not being in immediate relation with the blood-vessels, are especially prone to caseous change. So, too, in the suprarenal capsules the caseous nodules, if examined early enough, will be found to consist of the tubular spaces of the organ filled with their cells in a state of fatty degeneration. In the liver, on the other hand, the secretory cells, being in intimate relation with the blood-vessels, are not liable to this caseous transformation. Again, it is impossible to make a strict demarcation between syphilitic affections of the viscera and true cirrhosis. Even the typical gummatous of syphilis originates in and are surrounded by tracts of cirrhotic induration; and in other cases where true gummatous are not found, the only difference between cirrhosis and syphilis is that in the latter there is a greater accumulation of the new growth at particular points and a less general diffusion of it through the organ. Lastly, in some cases, as in the cirrhotic liver of hereditary syphilis, the two processes are identical.

If we now proceed to inquire into the causes of cirrhosis, we find that it is generally preceded by a protracted hyperemia of the affected organ produced by some chronic irritation, whether

functional or mechanical. As examples of this may be mentioned cirrhosis of the liver which results from the congestion produced by spirit-drinking; sclerosis of the grey matter of the cerebral convolutions after protracted maniacal excitement; cirrhosis of the lung, the result of prolonged inhalation of irritating dust in the various forms of grinders' and miners' phthisis; the cirrhotic thickening of the pylorus in chronic catarrh of the stomach; and cirrhotic affections of the lungs and heart extending to those organs in chronic inflammation of their serous coverings. A more passive congestion, however, if long continued, may cause a simple hypertrophy or overgrowth of the interstitial connective tissue, and more or less induration in consequence. It does not, however, appear to have the same tendency to excite active proliferation and the formation of the contracting fibrous tissue characteristic of true cirrhosis. The exception to this rule is that we usually meet with a slight degree of the cirrhotic change in cases of 'nutmeg' atrophy of the liver due to prolonged passive congestion of the hepatic venous system. W. CAYLEY.

CIRRHOSIS OF LIVER, LUNG, &c.
See LIVER, LUNG, &c., Diseases of.

CIVIL INCAPACITY. - One of the causes of this condition is mental weakness or disease, and it is one of the duties of the physician to aid in determining the existence and nature of such conditions. There is a kind of incapacity which is implied in the restriction of a person's liberty when he is placed under care in an asylum or other special place of treatment. The necessary information regarding this will be found in the article LUNACY, Laws of. But the question of incapacity is more directly raised when it is proposed that a person should be declared unfit to exercise his civil rights, to require the shield of the law to prevent his being imposed on, and to obtain special protection for his property. Medical evidence will require to be taken if it becomes necessary for a Commission of Lunacy to be issued by the Lord Chancellor. This is a proceeding which ought not to be adopted if it can properly be avoided. But it must be remembered that till a person is found insane by inquisition he may, though placed in an asylum under regular certificates, exercise his rights unrestricted in the disposal of his property. The acts of any person either in or out of an asylum may, however, be declared invalid if it can be shown that at the time they were performed the person laboured under such an insanity as rendered him incapable of performing them rationally and without injurious consequences. On this principle any person may be found to have been incapable of contracting marriage, of executing a deed, contracting a debt, making a will, or giving credible evidence. The principle, it must be carefully noted, is not that the mere existence of insanity in the person performing them invalidates such actions, but that if the insanity has materially affected the character and quality of the actions they may be thereby invalidated. This is one of the most important principles that a medical jurist has to keep in mind as it is not an unfrequent mistake to sup-

pose that a person is necessarily incapacitated for the performance of every civil act the moment he can be proved to labour under any condition to which the term insanity may be applied. Perhaps the case in which the validity of a civil act is most easily endangered by the existence of any form of insanity is the contract of marriage. This proceeding is supposed so to affect the whole relations of life that almost any form of unsoundness of mind may be sufficient to interfere with that intelligent and deliberate consideration which is essential to the giving of rational consent.

The different kinds of mental disease will be found described elsewhere (*see INSANITY*), and it is necessary that the practitioner, when dealing with medico-legal questions, should be fully acquainted with them. But it is chiefly important that he should distinguish the two following classes: (1) diseased perversion of the mental faculties, and (2) weakness or enfeeblement of the mental faculties resulting either from defective development, disease, or decay. The first class includes all kinds of insanity which are the result of active disease. These would be the simple forms of delirium, mania, melancholia, and monomania; as well as the similar primary conditions which are found in general paralysis, and other diseases which present maniacal, melancholic, or monomaniacal symptoms. It is in this class that the special knowledge of the physician can be most successfully applied in aiding the administration of justice. In order to establish the incapacity of a person said to labour under any of these forms of disease, it must be necessary that an experienced physician should not only be able to detect their characteristic symptoms, but also to show that the performance of the duties or the exercise of the rights under consideration would be modified or obstructed by the existence of such disease. The second class includes congenital imbecility, and all the forms of what is called chronic dementia—all those enfeeblements of mind which are sometimes the remaining effects of acute disease, sometimes the concomitants of chronic disease, and sometimes only the mental phase of senile decay. Here, again, the information which may be communicated by the physician must be of great importance. But in estimating the extent to which a condition of mere mental weakness will disable a person from the performance of a certain class of actions there is not so much special medical knowledge required as is necessary in the consideration of active disease.

Marriage.—As has been already stated, the mere existence of any form of insanity in one of the parties may render a contract of marriage void. In one case which terminated in this manner, a man who had been insane and when in that state had voluntarily contracted marriage instituted the suit himself.

Civil Contracts may be held binding although made by lunatics. If the person with whom a contract is made had no knowledge that the person contracting was insane, and if no attempt was made to take undue advantage of him, the contract would be held good.

Wills.—A person is considered to be of a disposing mind, that is, capable of making a valid

will, if he knows the nature of the act which he is performing, and is fully aware of its consequences. It is in regard to the making of wills that the law has carried out most thoroughly the principle that the validity of an act ought to be maintained in cases of insanity unless at the time the act is performed the state of mind of the agent can be shown to render him unfit to perform that particular act in a rational manner. Persons have made valid wills while inmates of lunatic asylums. And one will was held to be good though the testator had committed suicide within three days after its execution. The existence of delusion which has been regarded by lawyers as of such importance in cases of alleged insanity does not invalidate a will; for it has been declared to be 'compatible with the retention of the general powers of the faculties of the mind,' and to be 'insufficient to overthrow the will unless it was calculated to influence the testator in making it.' On the other hand, a will may be invalidated on account of the existence of mental states which would not be regarded as insanity from either a legal or medical point of view. Drowsiness and stupor resulting from erysipelas or fever, extreme weakness from cholera, and failure of memory in old age, have all been found sufficient to render wills void. It frequently happens that a medical man is called on to be witness to a will. On such an occasion it is his duty to satisfy himself as to the testamentary capacity of the testator. His subsequent evidence in regard to this will, in case of dispute, be of almost decisive influence if he has taken proper means of forming an opinion. In all cases, therefore, where there may be a possibility of doubt it is well to require the testator to show that without extraneous aid, and without referring to the document itself, he remembers and understands all the provisions of the deed.

Evidence of the Insane.—Lunacy was, till a recent date, regarded by the law as incapacitating a patient from giving evidence in court. But according to the much more extended significance on which the term lunacy has received it now includes states of mind which are looked on as compatible with testimonial capacity. Where the judge is satisfied that the lunatic understands the obligation of an oath, and can give a rational account of such things as happen before his eyes, the evidence may be admitted. But the weight to be attached to such evidence will still depend on the extent to which it fulfils the conditions commonly required to constitute credibility. It has been held, however, that when a person has suffered from an attack of insanity between the occurrence of the transaction and the time he tenders his testimony, his evidence cannot be admitted.

Management of Property.—Where persons are supposed to be unable from unsoundness of mind to undertake the management of their own property, it may be necessary that they should be placed under the protection of the Court of Chancery; but this proceeding is not usually had recourse to unless there is urgent necessity or a strong probability that the person's incapacity will be permanent. It is consequently resorted to chiefly in chronic or congenital cases where

there is no room for doubt as to the mental condition of the individual; and in cases of recent insanity where it is necessary to have recourse to an asylum for the protection of the individual it may also be necessary to obtain protection for his property by the aid of the Court of Chancery. In giving evidence or framing a statement in such a case it is important, if incapacity is to be proved, to show that the individual has been found, when placed in circumstances requiring such capacity, unable to perform the acts which the management of property necessitates. In cases of active insanity it is especially required to show, not merely that there is delusion or other symptoms of insanity, but that the insanity is of such a nature as specially to disable the person from duly performing the duties which would be required of him. Difficulties most frequently occur in cases of imbecility and dementia; but the verdicts in such cases when disputed will generally be found to rest rather upon the impression produced by evidence of the actual behaviour of the individual than upon the mere medical view of his mental condition. The most effectual aid that the medical witness can render in such cases is to show whether there are or are not such peculiarities in the conduct of the person under inquiry as are known to be characteristic of imbeciles or demented persons. In undisputed cases, where the duty of the medical man consists merely in making an affidavit, there is no special difficulty to be encountered. Brevity, scrupulous accuracy, and attention to the fact that such unsoundness of mind as involves incompetency to manage property must be established, are the most important requirements. A person found by the court to be incapable is placed under the control of a 'committee of the person,' and the property under a 'committee of the estate.' In Scotland an application to the Court of Session for the appointment of a *Curator bonis* takes the place of the English inquiry. The chief peculiarities of the Scotch process are that it is cheaper, more easily effected and more easily annulled, and that it does not affect the person of the lunatic. The functions of the curator correspond to those of the committee of the estate in the English court. The Scotch procedure for the appointment of a guardian of the person was virtually in desuetude until the passing of a recent statute (31 and 32 Vict., cap. 100). Under this act a brief for the cognition of an alleged lunatic is issued from Chancery and tried before a judge of the Court of Session and a special jury. The procedure is similar to that of jury trials in other civil causes in Scotland, and both medical and other evidence must be produced. If the person so cognosed be found 'furious, fatuous, or labouring under such unsoundness of mind as to render him incapable of managing his affairs,' his person is placed under the guardianship of the nearest male relative found competent.

Drunkenness.—This condition is not held to deprive a man of civil capacity unless it has at the time rendered the individual unconscious of what he was doing. J. SIBBALD.

CLAP.—A popular name for gonorrhoea. See GONORRHOEA.

CLAVUS HYSTERICUS (*clavus*, a nail).—An acute pain often associated with hysteria, but occurring also in other conditions, which is felt in a localised point in the head, and is compared by the sufferer to the sensation that might be produced by a nail being driven into the part. See HYSTERIA.

CLIMACTERIO (*κλιμακτήριον*, a step, *κλίμαξ*, I proceed by degrees, or step by step).—This word, which properly signifies 'by degrees,' was originally employed to indicate certain epochs or periods in the life of an individual, which were looked upon as critical, and at which the body was supposed to have undergone a complete change, so that it had become entirely renewed in its structural elements. The years in which these epochs terminated were called *climacteric years*—*anni climacterici*, and their number was variously estimated. Thus, some only recognised three climacterics; the Greek physiologists held that there were five, ending at the seventh year, the twenty-first (7×3), the forty-ninth (7×7), the sixty-third (7×9), and the eighty-first (9×9); others made them multiples of seven or nine, or multiples of seven by an odd number. Most regarded the sixty-third year as the *grand climacteric*, but the Greeks recognised two *grand climacterics*, terminating respectively at the sixty-third and eighty-first years, and this special denomination was given because there was little, if any, prospect of life being extended beyond these periods. At the present day the word *climacteric* has lost much of its original meaning, and is generally applied to certain times of life without any reference to numbers of years, at which marked physiological or developmental changes occur, such as the period of puberty, or that of the cessation of menstruation.

A particular *climacteric disease* has been described, which is said to occur either about or subsequent to the sixty-third year or *grand climacteric*, and supposed to be distinct from the natural decay and degeneration which takes place in advanced life, inasmuch as recovery often ensues. It is stated that the complaint comes on suddenly, but advances insidiously, the symptoms being at first loss of flesh and weakness, followed by loss of appetite and dyspeptic symptoms with a white tongue, which are regarded as sympathetic, sleeplessness or disturbed and unrefreshing sleep, constipation, pains in the head and chest, a frequent pulse, swelling of the legs, and an emaciated or bloated appearance of the face. The urine does not present any abnormal characters, and most of the viscera seem to perform their functions properly. Whether there is any independent disease deserving this special denomination seems to the writer to be more than doubtful.

FREDERICK T. ROBERTS.

CLIMATE, Etiology of. See DISEASE, Causes of.

CLIMATE.—Formerly the word *climate* (from the Greek word *κλίμα*, I incline) was a term of astronomical or mathematical geography, which implied a portion or zone of the earth's surface comprised between two lines parallel to the equator, and measured by the length of time during which the sun there appears during the

summer solstice, that is, by the sun's inclination. The space between the equator and the pole was divided into half-hour climates, in which the length of each day increased by half-an-hour, and also into monthly climates. This unequal division of each hemisphere is now replaced by a division of the interval between the equator and the poles into ninety degrees, which constitute what are called degrees of latitude, and the word climate has received a more extended application.

By climate is now understood those conditions of heat, moisture, atmosphere, wind, soil, and electricity, which impress certain conditions, uniform even when apparently irregular, on given portions of the earth's surface, and which modify, also in a uniform manner, vegetable and animal life.

Climate, when thus interpreted, is still principally dependent on astronomical facts, on the sun's position or inclination with regard to the earth, and on the amount of heat it supplies to different portions of the surface of the latter. Climate may be studied generally and locally. The division of the earth's climates is necessarily arbitrary, and many different classifications have been proposed. The most simple is that which recognises three principal kinds of climate, each susceptible of subdivision, viz.: warm climates from the equator to 35° lat., temperate climates from 35° to 50° or 55° lat., cold climates from 50° or 55° to the pole. As subdivisions we may recognise equatorial, tropical, sub-tropical, sub-polar, and polar climates; and also insular and maritime, or moist climates—continental and mountain, or dry climates.

1. *Warm climates*, extending from the equator to 35° lat., that is, 12½ beyond the tropics, comprise nearly all Africa and its islands, South Asia, most of the islands of Polynesia, and the portions of North and South America comprised between California and the north of the La Plata territory. In the equatorial regions the medium temperature for the year is from 80° to 84° F., the min being 64°, the max. 118°. Near the equator the annual mean temperature decreases slowly as we recede from it, the decrease not amounting to more than 2° F. for the first 10° lat. The difference of temperature during the day is slight, but much greater during the night, owing to radiation. The general variations of the barometer are slight, but the periodical or diurnal variations are very marked. It ascends and descends regularly twice in the twenty-four hours. It ascends from 4 13 a.m. to 9 23 a.m., and descends until 4 8 p.m., ascending again until 10.23. Electrical phenomena are very decided. The rainfall is variable, but 40 inches may be given as a mean. It is generally supposed that heat is greatest at the equator and diminishes as we recede from it; but both observation and astronomical induction lead to the conclusion that not only the maximum of temperature in warm climates is attained at or near the tropics, but also the highest annual mean. The countries in which the highest degree of heat is known to be attained are near the tropic of Cancer, as, for instance, the banks of the Senegal, the Tehama of Arabia, and Mehran in Beloochistan. Moreover, the snow-line, or the line of perpetual snow, is higher at the tropics than at the equator. In the Bolivian Andes, near the tropic, it is 17,000 feet, whereas in the

Ecuador Andes, on the equator, it is only 16,000 feet. These facts are partly explained by the unequal progress of the sun after the equinox in its course towards the tropic. In the first month it passes through 12° of latitude, in the second month through 8°. At the end of the second month, therefore, it is 20° from the equator, and there remain only 3½° to be traversed in the third month. The sun receding from the tropic at the same rate at all places between 20° and 23½° of latitude, the solar rays during two months fall at noon either perpendicularly or at an angle which deviates from a right only by 3½° at most.

Another cause which tends to diminish heat in the regions near the equator is the prevalence of rain. For about five degrees north and south of the equator, in the region of the equatorial calms, there are few consecutive days in the year without rain. The principal cause both of the calms and of the rains has been attributed to the meeting in the upper atmospheric regions of the trade winds, north and south. They neutralise each other and precipitate the vapour they hold in solution.

Regions that lie between 5° and 10° of latitude have usually two rainy and two dry seasons. The greater rainy season occurs when the sun in its passage to the nearest tropic passes over the zenith, lasting from three to four months. The lesser rainy season occurs when the sun on its return from the nearest tropic approaches the parallel of the place. The rains then only last from six weeks to two months, and are much less abundant and continual. Countries more than 10° or 12° from the equator have only one rainy and one dry season, the first begins when the sun approaches the nearest tropic, and ends some time after, when in its course from the tropic it has passed the parallel of the place. It lasts from four to six months. Local conditions may modify the course of the dry and wet seasons, as is the case in India, where the dry and rainy seasons depend principally on the monsoons. The amount of rain that falls in a short time within the tropics is very great, much more so than in more northern regions, but these heavy rains do not last continuously as is supposed. Days of continued rain, even in the rainy season, are rarer than in the north. Still, heavy rains are apt to cause great inundations, and to cover large extents of low or level country with water, causing swamps and marshes, very injurious to health.

In the vicinity of the tropics there is a belt, extending over several degrees of latitude, where it seldom rains. This rainless tract is precisely the region which has been already mentioned as that of greatest heat. These belts of rainless regions, extending around the globe on each side of the equator, may be said to separate the countries which lie on each side of the equator from the temperate zones. Thus in Africa the rains cease on the southern border of the desert of Sahara at about 16° N., and begin again at 28° N. On the banks of the Nile the rain ceases about 18° or 19°, to begin again between 28° and 29°. The Tehama, or low coast of Arabia, is all but rainless. This rainless tract crosses Asia as far as China, where there is no rainless region, owing, probably, to the fact, that all parts of China be-

tween 22° and 30° N. lat. are traversed by high mountain chains.

The influence of warm climates impresses certain peculiarities on the peoples who inhabit them. They are the abode of the Ethiopian and Mongolian races of mankind, and appear to have impressed the same characteristics, in a minor degree, on the Caucasian races that inhabit them: a dark complexion and black hair. The inhabitants of these countries are indolent and apathetic. The functions of the skin and liver are peculiarly active, a circumstance which exposes them to severe diseases of these organs. The digestive functions are sluggish, and the nervous system is alternately excited and depressed. Remittent and intermittent fevers, dysentery and yellow fever are common. During the dry season disease tends to assume the ataxic, during the rainy season the adynamic form. Pulmonary consumption is frequently met with in the towns, in contradiction to received opinions.

2. *Temperate climates* may be said to occupy the zones of the earth's surface comprised between 35° and 50° or 55° lat. They comprise southern and central Europe, with its islands; the parts of Asia which extend between the Black Sea and the Mediterranean, and Japan; the greater part of North America, a part of Chili and La Plata and Patagonia, in South America. The mean temperature may be stated at from 60° to 50°. The climates in which the mean temperature is from 60° to 68° are often spoken of as temperate, but in reality they approximate closely to warm climates. The four seasons, winter, spring, summer, and autumn, are well marked, but very variable both as to barometrical and thermometrical conditions. The mean temperature in the central regions is, for winter 38°, for spring 51°, for summer 68°, and for autumn 53°. The regions which are near the south and north limits of the temperate zones approximate to the meteorological characters of the warm and cold climates respectively. The periods of the year when storms, rain, and general versatility of meteorological phenomena are principally observed correspond with the vernal and autumnal equinoxes. The influence of a temperate climate on the human organisation is salutary, extremes of heat and cold being both trying. Thus the healthiest climates of the world's surface are found in this zone. Intense heat, or even moderate heat if persistent, throws a physiological strain on the liver, skin, and digestive system, and renders mankind prone to severe and fatal diseases of these organs. Intense cold throws a physiological strain on the lungs and kidneys, and exposes them also to severe and fatal disease. The healthiest temperate climates are those in which the winter is not very cold and the summer is not very warm, and in which, consequently, there is no great or continued strain on any one class of organs. The diseases of temperate regions are those that are the best known, as their study and description constitute the foundation of pathological science, ancient and modern.

The climate which, perhaps, the best deserves the appellation of temperate is that of the Mediterranean basin. The winters are not severe on any part of its north shores, and the summers are

not intensely hot on its south shores; at least the heat falls short of that of the tropics. There are many conditions of physical geography which conduce to this result. The north shores are protected from north winds by the ranges of high mountains of Southern Europe which skirt them, and the south shores are in close proximity to the hot, rainless tract of Northern Africa—the desert of Sahara, which favourably modifies winter temperature. Moreover, the Mediterranean is a warm sea, but few cold rivers of considerable size flowing into it from the north, a fact which increases the temperature on its shores and islands.

3. *Cold climates* comprise the regions which extend from 50° or 55° lat. to the poles. They may be subdivided into *cold*, with a mean of from 50° to 40°, *very cold*, with a mean of from 40° to 32°, *glacial*, with a mean below the freezing point. In the austral hemisphere the zone contains but little known land, although the existence of an antarctic continent is suspected; in the northern hemisphere it comprises, in Europe, the north of Scotland, Denmark, Sweden, Norway, Iceland, Finland, Lapland, Northern Russia, Spitzbergen, Nova Zembla; Northern Asia, and some of its large plains below 50° lat., Siberia, and Kamtschatka; in America, Canada, including some regions below 50°, the northern lands and islands of Hudson's and Baffin's Bays, and Greenland. In this zone the decrease of the mean temperature is much more rapid as we recede from the equator, than it is in the tropical regions. Thus from the equator to 20° lat. the variation of the mean temperature is not more than 7° or 8°, whereas the variation between 55° and 75° lat. amounts to from 22° to 27°. The coldest region of the globe is not, it would appear, at or near the pole, but at about 80° lat., or 10° from the pole, north of Behring's Straits: the cold of the glacial climates has been exaggerated. At the latitudes of from 70° to 78°, the extreme limit of human habitation, the mean annual temperature is between 19° and 17°, i.e. 13° to 15° below the freezing point. The extreme of cold registered, however, reaches a hundred degrees or more below the freezing point. Owing to astronomical conditions there is great disproportion between the length of the nights and of the days at different seasons of the year. In the more northern regions, for several months in the winter the sun never appears above the horizon, and in the summer for several months the sun never disappears below it. Spring, during which the extreme cold is mitigated, lasts but a very short time, and is succeeded by summer, which is in its full strength in June and July. Temperature rises rapidly from 35° to 55° and 60°. In some northern localities it rises to 86° or 90°. Under the influence of the prolonged or persistent days, and of the increased temperature, the vegetation peculiar to each locality passes through all its phases with extreme rapidity. Towards the end of July rain and fog reappear, and are followed by snow and intense cold, the highest expression of which is in January and February. The barometrical changes are the reverse of what obtains in the tropics. Above 60° lat. the diurnal or periodical changes are scarcely perceptible, whereas general or occasional variations become

more marked as we approach the pole. Electrical phenomena become less marked, and above 68° lat. they are scarcely perceptible, with the exception of the aurora borealis. The winds which predominate are the N.E. and S.W., and they change rapidly from one point of the horizon to the other, and thus frequently occasion tempests which extend over considerable areas. The quantity of rain that falls in cold climates is much less than in the tropical and temperate, with some exceptions. Between 60° and 90° lat. it only amounts to a few inches, and falls principally in the form of snow. The influence of cold climates is shown on the inhabitants of these countries, who vary much in stature, and possess a vigorous constitution, a sanguineous temperament, great muscular development, active digestive functions, and sluggish nervous powers. Notwithstanding the severity of the climate they generally succeed in protecting life, and live to old age, presenting few diseases peculiar to climatic influences. They are, however, subject to ophthalmia and amaurosis, owing to the reflexion of light from the snow in the polar regions, and to scrofula and scurvy, the result of a poor and incomplete dietary. Agues, and intermittent fevers from marsh influences, are rare, and not severe, and disappear entirely as we approach the pole. Continued fevers are met with, but seldom if ever epidemically.

4. *Insular climates* present important peculiarities. The temperature of the sea is more equable than that of the land. Owing to the action of currents, and to the circulation of its waters under the influence of heat, its superficial temperature is warmer in winter and cooler in summer—more equable—than that of the land. It has thus a tendency to warm in winter and to cool in summer the island which it surrounds. Moreover, there is constantly watery vapour arising from the sea which extends to inland atmospheres, veils the sky more or less, shields their surface from the ardour of the sun in summer, and prevents great radiation both in summer and in winter. Thus it is that the climate of all islands is more equable than that of continents. This fact is more especially recognisable in the climate of the British Isles, which is also modified—rendered warmer and moister, by the waters of the Gulf Stream impinging on their shores. The warm Gulf Stream, commencing in the tropics, in the Gulf of Mexico, passes northwards along the shores of North America, crosses the Atlantic to the south of Newfoundland, and strikes the shores of the British Islands, of Norway up to Cape North, of Holland, and of France; everywhere raising temperature and the annual mean.

5. *Maritime climates* participate in these influences; temperature is more equable, warmer in winter and cooler in summer, on the shores of seas and oceans than it is inland. Owing to this cause most of the winter sanatoria have been chosen in islands or on the coasts of oceans and seas: such as Hastings, Ventnor, Bournemouth, Torquay, Funchal, Malaga, Cannes, Nice, Mentone, Naples, Salerno, and Algiers.

6. *Continental climates* exhibit conditions the reverse of those which obtain in maritime climates. The tendency is to cold winters and

warm summers, owing principally to the absence of the equalizing influence on temperature of large masses of water. A very short distance from the sea is sufficient to establish this difference. Thus the central parts of France are very much warmer in summer and colder in winter than the coasts of Normandy and Brittany. But it is when we reach the centre of continents—Russia, central Asia, central America—that the difference is the most marked.

7. *Mountain climates*.—As we rise above the level of the sea, we meet with two important meteorological conditions. The air becomes more and more rarefied, and the heat diminishes, independently of the more or less obliquity of the sun's rays. The higher we rise above the sea level the more the air is rarefied, and the more the degree of heat due to the solar rays diminishes. We arrive at last, even at the tropics or the equator, at a height, variable according to latitude, where the sun's heat is insufficient to melt the snow. This is termed the snow-line. Mountains attract clouds and watery vapour, and the coolness of their atmosphere causes the precipitation of the vapour in the form of rain or snow. Thus, mountains, mountain-ranges, and the glaciers they contain, are the principal cause and origin of rivers. The influence of mountain climates, notwithstanding the clouds, fogs, and rain which characterise them, is proverbially a healthy one, owing to the purity of the air, and, perhaps, to the sparseness of population. They have of late been much recommended for phthisis. The two conditions above mentioned, however, namely, purity of the atmosphere and sparseness of human habitations, are quite sufficient to account for the rarity of phthisis amongst their inhabitants, and for the improvement of the phthisical who resort to them.

Soil modifies climate considerably. Wet and marshy soils are cold, engendering fog and mist. Sandy, dry, well-drained soils are comparatively warm. All sandy plains are warm in summer and cold in winter.

Such are the features which characterise the climates of the terrestrial globe, generally. Each locality, however, each mountain, plain, and valley, each city, village, and house, has a climate of its own, modified by all the meteorological elements which we have successively considered. To discover what each climate is, we must study carefully the meteorological conditions and influences which we have rapidly surveyed in their application to it.

8. *Isothermal climates*.—Owing to the unequal influence of the different elements that constitute climate, the annual mean temperature of regions occupying the same latitude on the earth's surface is very variable. Hence the above name has been given to the regions in which the annual mean is the same. The study of a map on which the isothermal lines are marked is an instructive illustration of the facts above described. Thus it will be seen at a glance that the limit of constantly frozen ground in the central plains of Asia and in the northern plains of America is below 54° F., which is the latitude of York!

The general influence of climate.—The vegetable and animal worlds, including man himself, have been modified in essential characters by

climatic conditions. The study of its influence on their vitality and organisation opens out a wide field to the observer. This study leads to the conclusion that geological periods of time have been necessary to impress on terrestrial life, be it vegetable or animal, the characteristics observed now or formerly in the climates of different regions of the earth. The current of modern research is strongly directed to the elucidation of the influence of climate on life during such geological periods. The investigations of Darwin and his followers may be named as the most remarkable and important illustration of this fact. We may also mention the researches of modern philologists, which have proved, by the study of languages and their roots, that most of the nations of modern Europe have descended from the same Aryan parents as the inhabitants of the Indian peninsula. Climate, in the course of time, has so modified them as apparently to produce different races. For such a change to take place geological lapses of time are certainly required. Our earliest records, dating back several thousand years, show those races such as they are now, quite as distinct. In these days the Aryan races of Europe cannot rear their children in the climate of India, where their Hindoo relatives thrive and propagate their species. In Palestine and Egypt the biblical records, those of the Pharaohs, and those of Nineveh and Babylon, show these regions to have been inhabited, several thousand years ago, by nations and tribes presenting precisely the same race characteristics as those that now inhabit them. During the historical period, the races of Europe have in vain endeavoured to colonise the valley of the Nile; but they have not been able to propagate their species, and have died away, leaving the valley of the Nile to its ancient inhabitants. Their children cannot withstand the heat of summer. On the north-eastern shore of Africa the Algerians of the present, history presents the same record. The Romans and the Visigoths occupied its plains for centuries, continually reuniting their colonies from the mother-countries, and yet, except in the mountains, all traces of their presence has disappeared. They could not rear their children so as to occupy the land of the Arabs. What lengthened periods of time must have elapsed to so profoundly modify races deriving their origin from a common parentage, that they can no longer live and propagate their species in the same climates!

Therapeutical Applications—The therapeutical application of many of the above facts is contained in the facts themselves. Reasoning suffices to deduce the therapeutical law, and experience proves the correctness of the deduction. A very brief summary only can here be given. See also CLIMATE, The Treatment of Disease by.

Firstly, it is clear that if a local climate produces injurious effects on the health of its inhabitants, or of visitors, the latter should leave it, and the regular inhabitants, who cannot leave it, should endeavour by every possible means to modify the pernicious climatic influence to which they are exposed, and to partially escape from its action. This rule may be illustrated by the influence of confined mountain valleys in pro-

ducing goitre, and of marshy districts in producing intermittent fevers. The principle applies to all local climates which exercise a pernicious influence of any kind on the human organisation. When possible the climate should be abandoned; if that is impossible its pernicious influence must be combated by every possible hygienic and therapeutical means.

The injurious effects which extreme climates exercise on the human economy—warm climates on the abdominal and cerebral organs, cold climates on the thoracic—point to change of residence as an important therapeutical agent, the value of which is only beginning to be understood. Our naval and military surgeons have done much to clear up this branch of therapeutics, as regards the diseases of tropical regions. Thus chronic affections of the liver and intestines incurable in a warm climate, often become curable if the patient is transferred to a temperate region or to a mountain elevation in the tropics, which reproduces a temperate climate.

Inversely, persons suffering from diseases of the respiratory organs, so common in damp temperate climates like those of France, England, and Holland, find relief by migrating, especially during winter, to warmer regions of the earth's surface, where they escape from the influences which have proved so detrimental to them. Thence the yearly increasing exodus of persons suffering from chronic laryngitis and bronchitis, from bronchial asthma and from phthisis, from the north of Europe to the south.

The increased facilities of locomotion, by rail and by steam, have thus opened out, as it were, a new and important branch of therapeutics, that of the application of climate to the treatment of disease.

J. HENRY BENNETT

CLIMATE, The Treatment of Disease by.—I though we can scarcely say with accuracy that change of climate is a specific for disease, yet much can be effected by it in relieving symptoms, and in assisting the reparative powers of the organism by thus improving the general health. The diseases in which change of climate has been found of value will be enumerated below, with a short notice of various climates. Here we may notice the *rationale* of the benefit to be derived from such change.

Change of climate, we must premise, is only a relative term. It does not necessarily involve the idea of removal to a great distance from the patient's home. A few miles' journey from the town to the country, from inland to the seashore, from the plain to the mountain, often suffices to produce marked results. One use of climate being to expose the organism to the effects of contrast, the element of distance comes in most when we wish to make the contrast greater; for instance, in ordering change from a cold to a warm climate or *vice versa*.

The therapeutic elements of most importance in any climate are (1) pure air free from dust and organic particles; (2) abundance of sunshine, without excessive heat, so that much time can be spent in the open air; (3) a temperature without extremes, so that the body is not exposed to the risk of great variations of heat and cold—equability; (4) absence of violent, very

cold, or very hot winds, at any rate of long duration (in this is involved the element of local shelter).

These four elements should be present in each of the subdivisions of climate which a therapeutic classification renders necessary, namely climate of (a) the seashore; (b) mountains; (c) inland wooded districts; (d) the open sea.

The epithets 'moist' and 'dry,' which are applied to climates, are merely relative, and depend on local peculiarities of rainfall, soil, &c., as well as to some extent on season; and the essential differences between the climate of the seashore, the woodland, and the mountain remain everywhere the same. We shall say a few words about each of these, with the indications for their use. The climate of the open sea will be referred to in speaking of sea voyages.

(a) *Climate of the Seashore.*—The special peculiarities of this variety of climate are that—the air is saturated with moisture, except when dry land winds prevail; it is dense, and, as a rule, therefore, bulk for bulk, contains more oxygen than air of any higher level, its density is liable to great and frequent but regular variations, which increase the activity of the circulatory and respiratory organs, and thus favour their functional activity; it is more equable, and, lastly, it contains saline particles in suspension.

According to Bencke, sea air cools the body relatively quicker than mountain air, and thus quickens the processes of tissue-change the most. Hence the seaside should be ordered where we wish for a highly stimulating effect, as in persons of scrofulous tendency, in chronic diseases succeeding acute ones, or in the later stages of convalescence from the latter, in convalescence from surgical operations, or in some surgical diseases where we wish to accelerate tissue-change, without exertion on the patient's part. On account of the equability of the climate, some patients who cannot bear great changes of temperature do well at the seaside. Persons suffering from overstrain, mental or bodily, with a fair digestive power, and not liable to nervous irritability, may also be sent there.

(b) *Mountain Climates* are distinguished from sea-side climates by the lower density of their atmosphere; their lower and less equable temperature; by less humidity, though, owing to local winds, mist and cloud often form; and by relatively lower night-temperatures in clear weather, owing to the dryness of the air, and consequent great radiation. They are cooler also than the inland climates of level districts, and this coolness tends to some extent to diminish the rarefaction and increase the density of their air.

The general action of mountain air is to produce a freer circulation of the blood and greater vascularity of the lungs, owing to deeper and more frequent inspirations and greater ease of bodily movement. Owing to the cooling of the body by the lowered temperature more food is required, the appetite improves, and the body becomes better nourished and gains weight.

The intensity of the effect is, roughly speaking, directly as the height. The term 'mountain climate' is applied in medical parlance to elevations in Europe of from 1,500 to 6,000 feet, though in South America patients have been sent as high as 10,000 feet, or higher.

Mountain Climates are indicated (1) in cases of hereditary tendency to phthisis in young persons with narrow, shallow chests, and who are growing too fast; also in young scrofulous patients. (2) In chronic phthisis and pneumonia; remembering, however, that phthisis occurs at all elevations. The coolness of the mountain air in the height of summer is an important element in phthisical cases, which always suffer from great heat. (3) As a tonic and restorative in persons suffering from over-work in business or literary pursuits, and who have no real organic disease. (4) Generally to complete the convalescence from acute diseases of individuals not past middle life, with a fair amount of muscular power and bodily activity. (5) As a prophylactic against hay-fever, cholera, and other infectious diseases. Mountain climates are not advisable in cases of chronic bronchitis, heart-disease, emphysema, Bright's disease, chronic rheumatism, or for aged persons.

(c) *The Climate of Wooded Districts* (elevations above 1,500 feet are not here referred to) is peculiar in the following points:—(1) It has a temperature lower than that of the surrounding country—on the average 3° Fahr.—during the hours of daylight; the temperature is also more equable. (2) The relative humidity is higher (9·3 per cent) in summer than in the less wooded country, and hence there is greater liability to rain and mist. (3) It affords greater protection and shelter against winds than other climates.

The general effect of woodland climates, as may be deduced from the above, is sedative and tonic. They may be advised in chronic bronchitis, emphysema, heart-disease, and in hypochondriasis, hysteria, and other nervous affections where tranquillity and subdued light are of importance; also in the earlier stages of convalescence from acute disease when sea or mountain air is too stimulating. In bronchitis pine woods should be selected, and in heart-disease level walks are essential.

(d) *Ocean Climates.*—*Sea Voyages* have of late years been much recommended in the treatment of phthisis in its early stages, with a view to enable the invalid to spend much time in an exceedingly pure and fairly equable atmosphere, and to secure a sufficient amount of bodily movement without great fatigue.

The main drawbacks to the sea are the impossibility of escape from bad weather and the confinement to close, ill-ventilated cabins, if such occurs; the absence of sufficient light and air below decks, the latter being felt very much at night; want of variety in the diet after a certain time, and at all times (except in short cruises, or coasting trips) of fresh food, milk, &c.; monotony in society and occupations; and, lastly, the inconveniences arising from crowding of the main-deck with hen-coops, sheep-pens, &c., and in steamers from the smoke of the engines, and the smell and vibration of the machinery.

The routes generally recommended to invalids are either to (1) Australia, 90 days; (2) the Cape of Good Hope, 30 days; (3) the West Indies, 14 days; (4) the United States or Canada (in summer), 10 days. Short cruises in the Mediterranean, or to the latitudes of the Canaries and Azores are suitable for certain

cases where expense is no object. Of routes (3) and (4) we may say that they are too short for the full benefit of the sea to be obtained, as improvement does not generally begin for a week or two after sea-sickness has subsided and the patient can remain comfortably on deck. Route (2) does not allow him to get the bracing effect of high South latitudes. Hence where a long sea voyage is indicated, route (1) is decidedly the best. England is quitted in the beginning of October, Australia (Sydney or Melbourne), or New Zealand (Wellington), is reached early in January, and the return voyage is begun not later than the end of February.

Patients should not remain in the coast-towns of Australia in summer on account of the heat. They should go to the table-land of New South Wales, or to Darling Downs in Queensland, or else they should cruise from port to port, or run over to New Zealand or Tasmania.

In returning, the route round Cape Horn should be avoided on account of the great risk of the climate of the South Pacific Ocean and the chance of encountering icebergs, fogs, and unfavourable winds. Either the patient should come back round the Cape of Good Hope, or if his strength permits he may cross to California, travel overland to New York and thence by steamer; or, lastly, he may come by the Red Sea, Suez Canal, and Mediterranean.

The invalid must expect about 20 wet days on the voyage out. The temperatures met with range from 40° to 80° Fahr, the coldest and most uncertain weather occurring in the North Atlantic and South Pacific Oceans.

Choice of Vessel.—The following considerations may be useful in deciding between steam and sailing vessels —

For a steamer there is the greater certainty in predicting the length of the voyage, and the calm of the tropics are sooner passed.

Against steamers, there is the nuisance of steam and smoke on deck; much space is taken up by the engines, stokers' rooms, &c., and hence other parts of the ship are more crowded, the bilge water is tainted with the engine grease, there is the wearying grind of the screw by day and by night, while more seas are shipped, because a steamer can run against a head-wind.

For sailing vessels there are the advantages of more room, light, and air in the cabins, and the absence of the above-mentioned disagreeable conditions.

Against them there is the longer and more uncertain duration of the voyage, and the necessity of shaping their course by the prevailing winds.

A word must be added as to the comparative merits of wooden and iron vessels. Briefly stated, iron ships are cleaner, drier, freer from smell of bilge water, and hence healthier than wooden; but on the other hand they are less equable in temperature (hotter in hot and colder in cold latitudes), and less aerated by natural ventilation through their sides than the latter. They are also noisier.

The vessel chosen should not be under 1,000 tons, and her age, class of passengers, the character, temper, and standing of her captain, as well as the size of her cabins, should be care-

fully ascertained. Of course it is a *sine qua non* that she should carry a duly qualified surgeon.

The cabin for the outward voyage to Australia should be on the port side, so as to get the breeze in hot weather, and *vice versa* in returning.

The cabin outfit should include a spring mattress, with hair (not wool) mattress over, a folding easy chair, chest of drawers, carpet, curtains, and sponge bath (Faber). Clothes of various degrees of thickness are essential, both for body and head, and a waterproof suit is necessary for bad weather.

Plenty of linen must be taken, as washing is difficult on board, and there should be a supply of preserved milk, meat or essence of meat, fruit, and light wines.

The *indications* for a sea voyage are hereditary tendency to phthisis, or the presence of actual but uncomplicated disease in a very early stage, in persons not past middle life, with a fair digestion, absence of severe pyrexia, and general health not much impaired. Patients with a tendency to hæmoptysis should not be sent, nor should those of a desponding disposition, who would thus be likely to suffer by the long absence from home, or from fears of their personal safety. Of course a tendency to protracted sea-sickness is a distinct contraindication.

The invalid should be careful not to overtax his digestion too much; he should take regular daily exercise on deck to the extent of his strength, have some definite occupation to beguile the time, and, if possible, be accompanied by a personal friend (Faber).

Choice of a Climate—General Hints.—It is a good plan, if possible, to order a patient a climate with that mean temperature and relative humidity which he is known to tolerate well (Sigmund). The patient's disposition must be considered, and a lively or a quiet place chosen according to his temperament. We should not send a poor man to a place beyond his means, otherwise he has to grudge himself many comforts, and loses much, if not all, the benefit of the change. In sending patients to the South of Europe this rule is too often neglected.

The special indications for the climates of particular places can only be understood by studying their local aspect. Generally speaking, as far as Great Britain is concerned, the climate of the east coast is colder and drier than that of the west and south coasts. In Europe the north and west coasts are moister and cooler than the shores of the Mediterranean. As to season, mountain and woodland climates are almost exclusively indicated in summer from May to September. Certain parts of the sea-coast are adapted for invalids at all seasons of the year; but as a rule the northern coasts of Europe and the eastern or south-eastern coasts of Great Britain are best suited for summer, and the south, west, and south-western for winter residence. The Mediterranean coast is only to be recommended from mid-October to the middle or end of May, and Egypt should be quitted not later than April. A word may be added as to the advantages of wintering in the South of Europe. It is incontestable that the invalid gets a milder winter, a longer autumn,

and an earlier spring. Although there is no place where some days of bad weather do not occur, or where uninterrupted calms are met with, yet the number of rainy days is fewer, there is more sun, little or no fog, and, except in the neighbourhood of the Pyrenees, little or no snow or ice. The scenery is picturesque and attractive, and the invalid is able to spend much time in the open air, and to sit out of doors on many days, even in mid-winter. The drawbacks to the South are the risk of chills owing to the difference between sun and shade temperatures, especially at first, when persons are unaccustomed to the climate, and fail to take sufficient care; the occasional occurrence of high winds, especially in spring; the more limited accommodation, owing to the expense of rooms and living; and the absence of many so-called 'home comforts.'

Those who visit the South must remember that the curative value of the climate consists in its *allowing much time to be spent in the open air*, and in its milder temperature and drier air, which protect the respiratory organs from fresh inflammatory attacks. A south room and warm clothing of the texture usually worn in England in autumn are essential, and a coat or wrap should always be carried out of doors in mid-winter to put on in passing from sun to shade. The invalid should strictly avoid the hot atmosphere of gaslit salons at night.

Patients with acute diseases of the respiratory organs should not be sent to the South; and high fever, excessive weakness, or the necessity of remaining in bed, are also contra-indications, owing to the fatigue and risks of the journey and the need of home comforts. Cases of mental disease with excitement, where rest and protection of the mind and body is of primary importance, should not be sent.

In the convalescence from acute diseases occurring in autumn, where a cold northern winter would prevent open-air exercise, and probably set up fresh exacerbations, southern winter climates are of great value.

In ordering change of climate the accommodation, food and water supply, soil and drainage of the locality chosen should be carefully considered, especially if the distance is a long one. The best climate may be unavailable for the invalid, owing to defects in one or more of these particulars.

Lastly, the patient's own feelings should be carefully consulted before he is sent far away from home. In some cases all the benefits of climate are counteracted by 'home-sickness.' *Celum non animum mutant qui trans mare currunt.*

Enumeration of Climates.—We shall now enumerate various climates and regions suitable for the treatment of cases that can be benefited.

1. **Of the Nervous System.**—In neuralgia, Arcachon (for the calm, sedative, yet tonic atmosphere of the pinewoods), Cannes (the districts away from the sea), Upper Egypt (Cairo, Luxor, Helwan), Hastings, Hyères, the Engadine, the Bernese Oberland, Pau, Pisa, Rome, the Salzammergat (Ischl, Berchtesgaden). Some of the above climates will also be found suitable to cases of hemiparesis and sciatica.

In hysteria, hypochondriasis, spinal irritation,

and in some cases of protracted chorea, Brighton, Cannes, Ischl, Malta, Mentone, Montpellier, Morocco (Tangiers), Nice, Naples, the Bernese Oberland (Grindelwald, Murren), Palermo, Pau, Seville, Spezia, and Valencia; the effect produced being chiefly due to diversion of the attention by the change of scene, although the bracing influence exerted on the system at large must be taken into account.

In chronic softening of the brain and spinal cord, in paralysis of cerebral origin and in some cases of locomotor ataxy the South of France may be advantageously ordered in winter, and Alpine climates of moderate height in summer. As a rule hot climates, or those where the sun has considerable power, are contra-indicated where there is a tendency to apoplexy or hyperæmia of the brain.

Temperate and bracing climates are, as a rule, to be recommended in nervous diseases, to restore the general tone of the system.

The immediate neighbourhood of the sea not unfrequently causes nervous excitement, neuralgia, and sleeplessness.

2. **Of the Respiratory and Circulatory Systems.**—In chronic bronchitis, emphysema, bronchial and spasmodic asthma, as well as in chronic pharyngeal and laryngeal catarrh and laryngeal ulceration the following climates may be recommended:—Algiers, Australia, the Azores, Bordighera, Bournemouth, the Canaries, the Cape of Good Hope (?), Upper Egypt, Glengariff, Hastings, Hyères, Lisbon, Madeira, Malaga, Malta (?), Mentone, Naples (?), Nervi, Nice, Palermo, Pau, Pisa, Queenstown, Rome, San Remo, Torquay, and Ventnor.

Change of climate is of great value in convalescence from the acute, and as a prophylactic and curative measure in the chronic forms of bronchitis, but we must remember that where there is copious expectoration a dry climate is indicated, while in the irritative forms with scanty sputa (*bronchitis secca*) a moderately moist mild climate is generally suitable. In emphysema we should choose a mild and not too dry climate, if possible in the neighbourhood of pine-woods, such as Arcachon, on the west coast of France. In spasmodic asthma the choice of climate must be partly a matter of personal experience.

In the early active, and in the quiescent forms of the later stages of phthisis, as well as in chronic pleurisy, and in convalescence from pneumonia, the following (chiefly winter) health resorts and climates have been favourably spoken of:—Algiers (?), Australia, Bordighera, Bournemouth, Cannes, Davos, Upper Egypt, Upper Engadine (in summer), South of France, Hastings, Hyères, Queenstown, Ischl (in summer), Madeira, Malaga, Mentone, Natal (?), Nervi, Nice (?), the Oberland (in summer), Palermo, Pau, Pisa, San Remo, Sicily, Spezia, Torquay, Glengariff, and the Undercliff (Isle of Wight).

In chronic endocarditis, pericarditis, and in heart-disease generally, a rather bracing climate, without extremes and of the character suited to chronic bronchitis, is usually indicated. Here both the tonic effects of climatic change and the prevention of pulmonary complications and fresh rheumatic attacks must be taken into account.

Mountain resorts of moderate height, well protected from sudden changes of temperature, may be prescribed in summer (von Dusch).

In the neuroses of the heart, including (1) angina pectoris, (2) palpitation associated with chlorosis, hysteria or hypochondriasis, and (3) exophthalmic goitre, bracing climates are indicated. In angina pectoris long journeys involving great exertion must be rigorously forbidden, as must also sightseeing or exciting amusements.

3. **Of the Abdominal Organs.**—In the various forms of chronic dyspepsia and intestinal catarrh, in chronic hepatic disease, in chronic dysentery (after removal from a malarial district or tropical climate), in diabetes, and in chronic endometritis, pelvic cellulitis, and other diseases of the uterus and its surroundings, the following climates may be selected from—Cannes, The Engadine, Hastings, Hyères, Lisbon, Malta, Mentone, Montpellier, Morocco, Naples, Nice, the Nile, the Bernese Oberland, Pontresina, the Pyrenees (in summer), Queenstown, the Salzammergut, Seville, Spezia, St. Moritz, Valencia, and Ventnor.

In convalescence from acute nephritis, and in all forms of chronic Bright's disease, but especially *catarrhal* nephritis, warm dry climates are indicated. Among the best are Upper Egypt, the Riviera, the Cape of Good Hope (inland), Bombay, and in England: Brighton, Folkestone, and Ventnor.

In renal calculus removal from particular districts in which stone is known to be prevalent may possibly be of use in some cases.

4 **Of the System at large**—Change of climate is here nearly always indicated.—

(1) In convalescence from typhus and typhoid fevers, scarlet fever (at the end of the desquamative stage), measles, diphtheria, and acute rheumatism; also in the third stage of protracted hooping cough.

(2) As a prophylactic against all infectious diseases, and especially cholera, yellow fever, huy fever, influenza, and malaria; also against rheumatism and phthisis by withdrawal from damp districts, and goitre and cretinism by removal from the *ensemble* of conditions to which the latter are due.

(3) In rickets, scrofula, chlorosis, general anæmia, and functional debility. Here, where a pure air and a bracing sunny atmosphere are the chief indications, the climates enumerated in section 1, page 268, are suitable, as are also Algiers, Biarritz (in autumn), the Cape of Good Hope, Ischl, Malaga, Rome, Seely, St. Moritz, and in Great Britain a number of inland and seaside places (Malvern, Seaborough, &c.) which we have not space to mention.

EDWARD I. SPARKS

CLINICAL (*κλινη*, a bed).—This word literally signifies 'of or belonging to a bed'; but it has been particularly applied to the practical study and teaching of disease at the bedside; and has more recently been extended to all that relates to the practical study of disease in the living subject generally.

CLONIC (*κλονος*, commotion).—This word is applied to spasmodic movements which are of

short duration, and alternate with periods of relaxation. See CONVULSIONS, and SPASM.

CLONUS. See SPINAL CORD, Diseases of; p. 1468.

CLOT.—A clot, or coagulum, is the product of the formation of fibrin. The separation or formation of fibrin is attributed to the union, under the influence of a ferment, of the fibrinogenetic substance or fibrinogen which is contained in the liquor sanguinis, the juice of the flesh and most of the serous fluids, with the fibrinoplastic substance which is contained in the blood-globules, the lymph-corpuscles, and the cells of the body generally. Coagulation of the blood within the blood-vessels is described under THROMBOSIS, the coagulation of extravasated blood under HÆMORRHAGE and BRAIN, Hæmorrhage into, and the coagulation of inflammatory exudations under INFLAMMATION and EXUDATION. See also BLOOD, Morbid Conditions of.

CLOTHING. See Disease, Causes of; and HEALTH, PERSONAL.

COAGULUM (*coagulo*, I encdle). See CLOT.

COAL GAS, Poisoning by.—Coal gas, so largely employed for illuminating purposes, is a compound, containing—in addition to olefant gas and analogous hydrocarbons, on which the luminosity principally depends—certain so-called diluents which burn with a non-luminous flame, viz., hydrogen, marsh gas, and carbonic oxide along with what are termed impurities, of which the chief are carbonic acid, sulphuretted hydrogen, and bisulphide of carbon. On these impurities the characteristic odour mainly depends. This odour, which is perceptible even to the extent of 1 in 10,000, is a valuable safeguard against accidents from escape of gas.

A mixture of coal gas with the air inhaled exerts a deleterious effect on the system, and proves fatal when it reaches a certain percentage. In addition to the danger from inhalation, fatal accidents frequently occur from the explosive nature of the compound which is formed when the gas reaches the proportion of 1 to 10 of the atmosphere. Much less than this, however (a non-explosive mixture, therefore), proves fatal if long inhaled.

It is difficult to determine the exact proportion of the gas present in atmospheres in which fatal accidents have occurred, but we derive important information on this point from experiments on animals. Many such have been made. M. Tourdes, who has carefully investigated the subject, finds that pure gas is almost instantaneously fatal; $\frac{1}{4}$ th kills rabbits in five minutes, and dogs in twelve minutes; $\frac{1}{4}$ th kills rabbits in from ten to fifteen minutes; $\frac{1}{10}$ th still proves fatal after a longer period; and evident signs of distress are caused in rabbits by an atmosphere containing only $\frac{1}{10}$ th of the gas. Dr. Taylor (*Edin. Med. Jour.*, July, 1874) has estimated the proportion of gas existing in a room in which a fatal case occurred at three per cent.

SUCKERS or POISONING.—Poisoning by coal gas is only known of as an accident. Occasionally suddenly fatal consequences ensue among workmen from exposure to a sudden rush of undiluted gas from gasometers and mains. More commonly slowly fatal cases result from the gas-

tap in a bed-room being left open carelessly, from accidental extinction of the light, or from leakage of gas-pipes in a house or at a distance, the gas gaining access to the house in the latter case through cellars, walls, and more especially by means of drains and sewer-pipes.

SYMPTOMS.—Gas, even when in comparatively small proportion and just sufficient to cause an unpleasant odour, acts deleteriously if long breathed, and gives rise to headache and general depression of health.

In severe and fatal cases the symptoms which have been noted are headache; nausea or vomiting; vertigo; and loss of consciousness, passing into deep coma and muscular prostration, which resembles the apoplectic state, the individual lying insensible and incapable of being roused, with livid features, stertorous breathing, and froth at the mouth. Death usually occurs quietly, in this state of coma, but occasionally with convulsions.

The state of the pupils does not seem to be constant, though they are generally dilated before death.

In Dr. Taylor's case the teeth were firmly clenched, and the eyes were in a constant state of lateral oscillation.

FATAL PERIOD.—The fatal period of poisoning by coal gas is extremely variable, and a remittent character of the symptoms sometimes gives rise to fallacious hopes of recovery in cases which ultimately prove fatal.

DIAGNOSIS.—The smell of gas in the clothes, breath, and perspiration, which continues for a considerable time after removal from the infected atmosphere, is the best indication of the cause of the coma.

ANATOMICAL CHARACTERS.—The smell of gas is often very marked. M. Tourdes has found, as the most constant appearances, a dark colour of the blood, which, however, coagulates; a bright colouration of the pulmonary tissue; froth in the air-passages; congestion of the mucous membrane at the base of the tongue more particularly; engorgement of the cerebral and spinal venous system; and rose-coloured patches on the thighs.

MODE OF ACTION.—It is obviously impossible to differentiate between the effects of the various constituents of coal-gas, but we have good reason for believing that the most active agent is the carbonic oxide, which exists in the proportion of from five per cent. (English gas) to twenty-five per cent.

The symptoms in the main agree with those caused by carbonic oxide (*see* CARBONIC OXIDE, Poisoning by), and the effects, therefore, would be chiefly due to the action of the carbonic oxide on hæmoglobin.

TREATMENT.—Instant removal from the infected atmosphere is the first thing to be attended to. Attempts must then be made to cause oxygenation of the blood by artificial respiration and stimulation of the respiratory centres by reflex stimulation of the face, chest, &c.

Such oxygen gas may be administered. As, however, the compound which carbonic oxide combines with the blood-colouring matter is a very stable one, and not easily broken up by the introduction of atmospheric air or oxygen, it not unfrequently happens that these measures prove

of no avail. In such cases it would be highly advisable to perform venesection, and then transfuse fresh blood, a plan of treatment which has been found successful in poisoning by carbonic oxide.

D. FERRIER.

COARCTATION (*coarcto*, I straiten).—

A pressing together, narrowing, or stricture of any hollow tube, such as the aorta, intestine, or urethra.

COLD, A.—A popular name for Catarrh. *See* CATARRH.

COLD, Ætiology of. *See* DISEASE, Causes of.

COLD, Effects of Severe or Extreme.—

The general effect of exposure to severe or extreme cold is to lower, even to extinction, all vital activity. The blood-vessels, especially the smaller arteries and capillaries, after a brief period of congestion, become contracted, the latter to such an extent as no longer to permit the passage of the red corpuscles; the normal condition, composition, and structural integrity of the various tissues are more or less impaired, or altogether destroyed; and those processes of chemical and physiological change which are essential to every manifestation of life, being only possible within certain very narrow limits of temperature, are hindered or absolutely prevented.

EFFECTS AND SYMPTOMS.—The more special effects vary in degree and kind:—1stly, with the degree of cold, the duration of the exposure, and the medium or manner of application, 2ndly, with the part, and extent of surface exposed, and, 3rdly, with the general constitution and physiological condition of the sufferer. Moderate cold, acting during a short time, or even severe cold during a still shorter time, followed by the glow of speedy reaction, exercises a tonic and stimulating influence. But if the cold is too severe, or the exposure too long, no glow of reaction occurs, but a sense of depression is experienced, from which, at best, recovery takes place but slowly. Continued exposure to such degree of cold as is yet not incompatible with the maintenance of life, nevertheless keeps at low ebb activity of nutrition and function alike. Extreme cold and long exposure lead to congelation and consolidation of the various tissues of the body. After complete congelation recovery is impossible. Dry cold is much less readily injurious in its influence than cold associated with wet. The better conductor of heat the medium is, the more speedily and completely does it reduce the temperature of the part with which it is in contact. Immersion in water cools more rapidly than exposure to air of the same temperature. and contact with wool, wood, or metal, of the same degree of coldness, excites in each case a different sensation, and leads to a different result, or to the same result with very different rapidity. Constant renewal of the medium in contact hastens the cooling effect; and a continuous draught of only moderately cold air may do more to chill than temporary exposure to an intensely cold, but still atmosphere. If some external part, and a comparatively small extent of surface only, be acted upon, the effect may be simply local, and

the general disturbance of the system scarcely appreciable. But if the whole body, or a considerable extent of surface, or any important internal organs be acted upon, a proportionately serious general effect is produced. The young (infants especially) and the aged alike ill sustain exposure to cold, and are most liable to suffer, not only from its direct effects, but also from the various maladies to which it gives rise. The feeble, ill-nourished, and broken in health, especially the subjects of organic disease, or of degeneration due to habitual intemperance, readily succumb, or only slowly and imperfectly recover. Among the healthy and otherwise vigorous, hunger, fatigue, sleep, anxiety of mind, fear and mental depression of whatever kind, lower—too often even to fatal issue—the power of resistance to the deadly influence of cold.

For local effects of exposure to cold see CHILBLAIN, FROST-BITE, and GANGRENE.

The General Effects produced by exposure to severe or extreme cold vary somewhat in different cases. Temporary exposure produces, first, a sense of coldness or chilliness, associated with paleness and corrugation of the skin (the so-called *cutis asserina*), then shivering and tingling sensations, followed by numbness and diminution of muscular activity and power. Healthy reaction restores more or less quickly the normal condition. Prolonged exposure to extreme cold gives rise to a series of symptoms, graphically described by Beaupré somewhat as follows: Reaction has a limit, and a moment arrives when the powers are exhausted. Shiverings, puckerings, paleness and coldness of the skin, livid spots, muscular flutterings, are symptoms of the shock given to the vital forces; syncope approaches; the stiff muscles contract irregularly; the body bends and shrinks, the limbs are half-bent; lassitude and languor invite to repose; a feeling of weight and numbness retards the steps; the knees bend; the sufferer sinks down or falls; the propensity to sleep becomes irresistible; everything grows strange; the senses are confused; the mind grows dull, the ideas incoherent, and the speech stammering or raving; respiration, at first interrupted, becomes slow; the heart's action is feeble, quick, hard, irregular, and sometimes painful, and the pulse progressively smaller; the pupils dilate; the brain becomes stupified; and finally deep coma indicates the approach of inevitable death.

Other, and somewhat different effects and symptoms, attributable to differences of circumstances and condition, have been from time to time observed. Distressing and almost intolerable thirst, with loss of appetite for food, is often experienced; and the attempt to obtain relief, by sucking snow or ice, only adds to the suffering. Somnolence is by no means so constant an effect as is commonly supposed—at any rate, in the earlier stages, and less extreme cases. On the other hand, inability to sleep has proved a common cause of suffering and consequent loss of strength. The manifestations of brain-disturbance due to exposure to cold, varying as they do from dullness, incoherence, wandering and thickening of speech to even raving delirium, are especially worthy of note, inasmuch as they re-

semble, and are liable to be mistaken for, the effects of alcoholic intoxication.

Death from the direct and immediate effects of cold is rare in our country; but it is estimated that in the Russian Empire, on an average, 694 deaths occur annually from this cause. The length of time during which exposure can be sustained varies greatly with the condition of the individual and with surrounding circumstances, as well as with the degree of cold. Under ordinary circumstances, an hour's exposure to intense cold often suffices to determine a fatal result. At the same time, well-authenticated cases are on record, in which persons buried, for days even, in the snow, have nevertheless survived and ultimately recovered with little permanent damage.

Mode of Death.—The immediate cause or mode of death from cold seems in some cases to be principally shock; in some, syncope; in others, asphyxia; and in others, again, coma. In most cases it is probable that these several conditions, with others less readily specified, combine to produce the fatal issue.

ANATOMICAL CHARACTERS.—The appearances presented on post-mortem examination are somewhat differently described and estimated by different observers; but none of them are absolutely pathognomonic, and some are as likely to be produced by exposure of the body after death as during the process of extinction of life. Among the more noteworthy are the following:—strong cadaveric rigidity, paleness or waxy whiteness of skin, with patches of more or less bright redness about the face, neck, and limbs, especially on exposed or prominent parts; a contracted and shrunken condition of the male genital organs, comparative bloodlessness of superficial and external parts; accumulation of blood in and about the thoracic and abdominal viscera; great distension of all the cavities of the heart, with more or less clotted and often bright-coloured blood, the blood in other parts also sometimes of brighter colour than usually seen on post-mortem inspection; hyperæmia and congestion of the lungs; hyperæmia of the brain, overfulness of the sinuses, and excess of serum fluid in the ventricles, and at the base, in some cases; in others, comparative bloodlessness of the surface of the brain, and no distension of the sinuses; excessive fullness of the urinary bladder; and, lastly, separation of the cranial bones along the coronal and sagittal sutures. The lines of reddish or brownish staining along the course of the superficial blood-vessels, relied on by some as pathognomonic, are certainly not so, inasmuch as they depend upon exsiccation of the blood colouring-matter set free by disruption of the corpuscles, which may be effected by freezing after death, as well as before.

TREATMENT.—The treatment of sufferers from the effects of cold, consists in the restoration of warmth, and the rekindling of those processes by which the natural heat of the body is maintained. But this must be done gradually, and with great care. As in the treatment of a frostbitten part, so in the treatment of the body generally, all sudden or rapid elevation of temperature must be avoided. The sufferer, divested of the clothing previously worn, and wrapped in blankets, should be placed in the recumbent position in a room,

the air of which is dry, still, and cold, but capable of being gradually warmed. Gentle, but continuous friction should be made over the trunk and limbs, care being taken that rigid or frozen parts be not damaged by rough manipulation. At first, ice or ice-cold water may be used; afterwards dry rubbing with flannel or with the hands is better—later still some stimulating liniment may be employed. Some recommend immersion of the body in a bath of cold—at first ice-cold—water, the temperature of which can be gradually raised. This method would seem easy and advantageous, if means are at command. When the sufferer can swallow, warm, gently stimulating, drinks—as tea, coffee, aromatic infusions, beef-tea, or soup—may be given, at first without, but later with some wine or spirit. Alcohol, though useless or injurious if taken to fortify against cold, is useful and beneficial when judiciously administered as a restorative after exposure. In all cases of insensibility, and even apparent death from cold, every effort must be made to restore animation, and the attempt must be persevered in for a considerable time before being given up as hopeless. It is often difficult, sometimes impossible, to judge whether life is absolutely extinct or not. And while, on the one hand, it is important that the temperature be not raised too quickly, lest reaction should be too strong or dangerously irregular; on the other hand, it is equally, if not more important, that the needful measures be adopted without delay, and carried out not too slowly, lest the chance of revival should be lost. In the less severe cases, restoration of warmth may be comparatively quickly accomplished. The state of the bladder should always be examined, and relief afforded, if needful, by aid of the catheter. Attention to the general health is often requisite for long after recovery from the more immediate effects of exposure has taken place. Rest, good nourishment, and tonics are indicated.

Cold as a Cause of Disease.—As a predisposing and exciting cause of disease, cold proves, in this country, year by year, more fatal in its effects probably than any other single condition or influence. Any considerable fall in the thermometer below the average standard during the colder months of the year is constantly followed by a corresponding rise in the death-rate, and an increase in still greater proportion in the amount and extent of sickness and suffering. The Reports of the Registrar-General clearly prove this, so far as the death-rate is concerned. A striking instance may be quoted. In the week ending December 19, 1863, in the London district 1,291 deaths were registered. Severe frost set in, and in the week ending January 9, 1864, the number rose to 1,798. The week following, ending January 16, no fewer than 2,427 deaths were registered. This enormous increase could be attributed to no other cause than the effects of the severe cold which prevailed. The Registrar-General also shows that after the age of from twenty to forty the mortality from cold increases in something like a definite ratio with increasing years.

General depression of the vital powers, congestion and functional derangement of various internal organs—the lungs, liver, and kidneys—

catarrhal and other forms of inflammation of the mucous membranes, especially of the respiratory tract, but also of the intestinal canal and bladder, paralysis from central or peripheral lesion, together with rheumatism, chilblain, frost-bite, and gangrene, constitute the list of maladies most commonly caused and fostered by exposure to the influence of cold. **ARTHUR E. DUKHAN.**

COLD, Therapeutics of.—The therapeutic uses of cold are various and extensive. Cold may be applied as moist cold, by means of wet compresses and cold lotions or baths; and it may also be used as dry cold in the form of ice enclosed in a receptacle of metal or india-rubber. Each of these methods has its special advantages and adaptations. Furthermore, cold may be made use of by the mouth, and by injection into the mucous canals of the body.

GENERAL PRINCIPLES.—The general effect of cold, however applied, is to lower temperature, to diminish sensibility and fluidity, to contract the tissues and vessels, and so to reduce the volume of parts. The cold bath and cold sponging alike have the effect of lowering the temperature of the body. The fall of temperature sometimes is but transient, reaction setting in and heat of surface returning when the body is withdrawn from the cooling medium. At other times the temperature continues to fall after the individual is removed from the bath. If the action of the cold bath be prolonged, then a thermometer, introduced within the rectum, shows a great depression of temperature, and much pain is experienced, similar to the severe pain which is felt in the hand and arm when the former is held for some time in water at a temperature of 41° Fahr., and which soon compels the withdrawal of the hand from the vessel. Cold baths and their uses are treated of in another article, but attention may here be drawn to the practice of cold sponging over the surface as an efficacious means of lowering proternatural heat and relieving acidity and dryness of the skin during fever. Reduction of hyperpyrexia by means of cold is now a well-established therapeutic method. *See TEMPERATURE, and Special Diseases.*

METHODS OF APPLICATION AND USES.

1. Cold Affusion and Wet Packing.—In the practice of cold affusion, introduced by Dr. Currie, in 1797, the patient is unclothed, seated in a tub, and four or five gallons of cold water thrown over him. Thus, Dr. Currie said, a commencing fever might be 'extinguished.' In cases where the skin was burning hot and dry, it was observed that after the cold affusion, temperature fell, perspiration broke out, and the patient usually dropped into a refreshing sleep. If the body-heat did not exceed 98.5° Fahr., or if the patient was damp and chilly, with or without delirium, the cold affusion was regarded as dangerous and by all means to be avoided. In fevers complicated with any visceral inflammation, the cold affusion is prejudicial. Drs. Strauss and Hirtz speak most highly of the marvellous effect of cold affusion in cases of collapse during fever. This kind of collapse appears due to a paralysis of the nervous centres: the heart's action fails, as does also the respiration; but while the surface of the body is cold, the temperature, taken in

the rectum, still remains abnormally high. The affusion is applied by pouring a pitcherful of water, at a temperature of, or a little above 10° C. (50° Fahr.), over the patient seated on a waterproof cloth. The patient, plunged in stupor, is suddenly roused by the shock; he draws a long breath, the respiration becomes fuller; the cardiac staxi ceases, and the pulsa, which, traced by the sphygmograph during the collapse, presented a scarcely broken horizontal line, now regains its normal line of ascension, heat of surface returns, and the temperature in the rectum falls. The action of the cold affusion, as thus applied, is to excite immediate and energetic reflex action.

In many nervous affections, such as chorea and hysteria, cold douches, shower baths, and affusions are valuable as restorative and curative agents. In the convulsions of robust children, a stream of cold water directed over the head from a height of two or three feet often has a speedily beneficial effect. Cold affusion has been tried in tetanus, but it has in some instances killed the patient (Elliotson).

Other cases in which cold affusions are of service are those where respiration fails, and it is necessary to appeal powerfully to the reflex excitability of the nervous centres. To resuscitate those who are in danger of death from a narcotic such as chloroform or opium, slapping the patient severely with a cold wet towel is an efficient method. In sun stroke cold affusion over the head and neck may be resorted to, provided the skin be not cold and clammy and the patient in a very syncopal state. In conditions of nervous spasm, of the larynx for example cold douches over the neck may prove useful. Cold affusion to the feet was much commended by Cullen as a means of promoting action of the bowels in cases of obstinate constipation. Spasmodic retention of urine has been relieved by cold douche over perineum and thighs (Currie), and Mr. Erichsen mentions the case of an old man who found his power of micturition increased by sitting on the cold marble top of his commode.

In cases of extreme debility, with damp, cool skin, low muttering delirium, and very feeble pulse, cold affusions are dangerous.

In some cases of fever, where for any cause a cold bath is objectionable, the patient may be wrapped in a wet sheet and then covered with a few blankets. The sheet as it becomes heated may be changed for one fresh and cold, or very cold water may be squeezed from a sponge over the sheet as the patient lies rolled up in it on a waterproof cloth. In scarlet fever of malignant type, where the rash does not readily appear, this form of cooling pack has been found most valuable. Drs. Hillier and Gee have both adduced their testimony to its utility. In Dr. Gee's cases the patient remained packed in the wet sheet for one hour and was then removed to bed. The cases best suited for treatment by the wet pack are those where the skin is very dry and hot, and the patient exceedingly restless and delirious.

2. Cold Compresses, Irrigations, Lotions, and Injections.—Cold may be continuously applied with a view to abating undue heat of a part of the body. Thus ice-water rags or compresses may be placed over an inflamed throat, or on

the head in inflammation of the brain. In acute pneumonia Niemeier has commended strongly the use of cloths dipped in cold water, well wrung, and then applied so as to cover the chest and especially the affected side. These compresses are repeated every five minutes. Pain and dyspnoea are much relieved; sometimes the temperature falls an entire degree; and if the cold appliances do not arrest the actual attack of pneumonia, they shorten its duration and promote speedy convalescence. The necessity of so often having to change the compress, and thus disturb the patient, is a great objection to this mode of applying cold.

A powerful sedative and antiphlogistic effect of cold can be obtained by *irrigation*; i.e. allowing cold water to fall drop by drop on a cloth, so as to keep it continually wet with fresh supplies of water. This may be done by suspending over the part to be irrigated a bottle of water, in which a few pieces of ice may be put; one end of a skein of cotton, well wetted, is then allowed to hang in the water, while the other end is brought over the side of the bottle. Thus, acting as a syphon, causes a continual dropping upon the part to be irrigated. In injuries of joints, where it is of much consequence to check inflammation, this process, which abstracts heat gradually, and without disturbance of the part, is most valuable. Irrigation of the shaven scalp in cases of meningitis is a very powerful, cooling, and sedative appliance, requiring care and watchfulness. A cup of india-rubber over the head and back of neck, so arranged that a current of cooled water may flow continuously through it, will act as a general reducer of temperature. Where pounded ice is applied to the head in a bladder, this should be suspended by a string from the bedstead, so that the head of the patient may not have to sustain the weight of the bag and its contents. Five ounces of sal ammoniac and five ounces of nitre in a pint of water will form a frigorific mixture, which can be applied in a bladder when ice is not at hand. The ice-bag, and cold water compresses renewed every three minutes, have been used as an appliance to strangulated hernia, and to prolapsed rectum, to reduce the volume of the part and so facilitate reduction. Care must be taken that the cold application be not continued so long as to cause gangrene. Cold wet compresses should not be applied over dry bandages, with which wounded or broken parts are secured. Several cases are recorded where a hand or arm has become gangrenous, in consequence of having been bound up with dry bandages, and then treated with cold water compresses. The dry bandages, as they become wet, contract tightly on the limb, thus stopping circulation and causing gangrene.

A mixture made of spirit of wine and water, or of eau de cologne with water, is a simple form of *cooling lotion*. The spirit evaporates and so carries off heat from the surface. 1 oz. of rectified spirit to 15 of water makes a good spirit lotion, and the addition of 4 drachms of nitrate of potash, or chloride of ammonium, will add to its cooling and sedative effect. 4 drachms of the chloride of ammonium with half an ounce of diluted acetic acid, and the same

quantity of rectified spirit in 15 ozs. of camphor water, is another form for a very serviceable lotion. These lotions, applied by means of a piece of soft rag or lint over the skin, act as refrigerants, cooling the head when it is hot or painful; reducing heat and arterial excitement in tumours or contusions; and tending in the latter to promote the absorption of effused blood. Cold water, and cold lotions of vinegar and water, are familiar means for trying to stop hæmorrhage.

In cases of severe uterine hæmorrhage, injections of ice-cold water into the vagina, or into the rectum, frequently succeed in checking the bleeding. In cases of bleeding internal piles an injection of cold water, after the action of the bowels, braces the parts and constricts the bleeding vessels.

3. Dry Cold. Uses of Ice.—Heat may be continuously abstracted from an inflamed part in a safe way, and without undue risk, by applying dry cold by means of a waterproof bag of vulcanised india-rubber filled with ice, snow, or a freezing mixture made of equal parts of salt, nitrate of potash, and chloride of ammonium. Moisture from the air will condense on the exterior of the cold bag, but a piece of lint interposed will protect the skin from damp. The india-rubber is a bad conductor, and too great abstraction of heat need not be feared. The walls of an animal bladder conduct heat much better than the india-rubber, and it is necessary to watch carefully over the application of ice-bladders, for when continuously applied they have been known to cause severe frost-bite of the part. If, when cold is being applied, the patient persists in complaining of severe pain, it is right carefully to examine and see how the part is affected by the cold. Professor Fearnach, in cases of fracture, and in various forms of traumatic inflammation, has applied ice for periods of twenty or thirty days with the best results. In cases of commencing disease of the vertebrae this surgeon has used cold water placed in a tin vessel, so made as to adapt itself to the part to be treated. Minor cases of bruise with inflammation may be treated by cold employed in the form of a common bottle filled with cold water and kept pressed against the part. After operations upon the eye, the extraction of cataract for example, a small ice-bag is very useful in relieving pain and keeping down inflammation.

Ice-bags placed along the course of the spine have been found effectual remedies in many forms of nervous disorder. In cases of epilepsy, where the circulation is sluggish, the hands and feet being always clammy and cold, an india-rubber bag of ice applied along the spine has been found to restore warmth, at the same time relieving headache and symptoms of incipient paralysis. Cold to the spine is asserted by Dr. Chapman to lessen the excitomotor power of the cord. In the severe pain of an inflamed ovary or testicle ice in a bag may often be employed beneficially as an anodyne.

Lumps of ice swallowed are invaluable in arresting hæmorrhage from the throat and stomach. In tonsillitis and diphtheria this same treatment tends to reduce inflammation and cool the throat of the patient. Obstinate vomiting can

often be checked by swallowing fragments of ice.

4. Cold as an Anæsthetic.—Dr. James Arnott, in 1849, brought forward the use of a freezing mixture of ice and salt as a means of producing local anæsthesia, by freezing the part to which the mixture was applied, either in a bag or in a metallic spoon. For small superficial operations this method of anæsthesia by congelation answers very well. The part becomes white and hardened to the cut of the surgeon's knife, there is very little hæmorrhage, and the wound made usually heals well by primary adhesion.

More recently, Dr. Richardson has indicated a very convenient way of inducing local anæsthesia, by the volatilization of ether in the form of spray, by means of the hand-ball spray atomizer. Ether sprayed on the bulb of a thermometer, held about an inch from the jet, brought down the mercury to within 10° Fahr. of zero. When the jet was turned on to the skin, a marked degree of local anæsthesia was produced, but not enough for surgical purposes. By driving over the ether under atmospheric pressure, instead of trusting simply to capillary action—or to suction, as in Siegle's apparatus—one may bring the thermometer within thirty seconds to 4° below zero. By the use of this apparatus, at any season or temperature, the surgeon can produce cold even 6° below zero; and by directing the spray upon a half-inch test-tube containing water, he can produce a column of ice in two minutes. For local anæsthesia by cold, the ether spray answers well. Such operations as the removal of small tumours, opening abscesses, and inserting sutures, may be painlessly performed. JOHN C. THOROWGOOD.

COLIC (κῶλον, the large intestine).—Originally colic signified a painful affection due to spasm of the bowel, but though still retaining this application, it has now come to be further associated with other complaints which are attended with severe pain of a spasmodic character, a qualifying adjective indicating the nature and seat of each particular form. Thus *renal colic* is applied to the group of symptoms due to the passage of a stone from the kidney to the bladder; *hepatic colic* to those accompanying the escape of a gall-stone. See COLIC, INTESTINAL.

COLIC, INTESTINAL.—SYNON.: *Fr.* Colique; *Ger.* Die Kolik.

DEFINITION.—Painful and irregular contraction of the muscular fibres of the intestines, without fever.

ÆTIOLOGY.—*Predisposing causes.*—These include the nervous (as hysteria, hypochondriasis), lymphatic, and bilious temperaments; sedentary occupations; the female sex; and the period of youth or adult age. *Exciting causes.*—These may be grouped as follows.—1. Irritation from lodgment of gas due to fermentation of undigested food and decomposition of feces long retained within the large intestine; from feces, or intestinal concretions, undigested or partly digested food, such as pork, shell-fish, salt meats, unripe fruit or septic game; from cold drinks or ices; from excessive or morbid secretions, especially bile; from gall-stones; or from worms—a bundle of

round worms or coiled up tape-worms. 2. Morbid states of the bowel, including obstruction from intussusception, twisting, strangulation, &c.; ulceration (typhoid, tubercular, dysenteric); inflammation (enteritis, typhilitis, &c.) 3. Reflex nervous disturbance, due to anxiety, fright, anger, or other emotional disorder; to disease of the ovaries or uterus; to calculus (hepatic or renal); to dentition; or to exposure, especially of the feet and abdomen, to cold. 4. Blood-poisoning, as from lead, copper, gout, rheumatism.

SYMPTOMS.—The characteristic or essential symptom of intestinal colic is pain in the abdomen, without febrile disturbance. It usually begins, and is most severe, in the umbilical region, then spreads to other parts, or to the whole abdomen, and is apt to travel from one part to another. It is almost always relieved by firm pressure and by expulsion of flatus, and is paroxysmal in character, remitting, or exacerbating, or completely subsiding at intervals. The suffering is usually severe, often agonising, and to relieve it the patient bends forwards, pressing the abdomen firmly with his hands or against some hard surface, or rolls about. As a rule the abdomen is distended by flatus; in lead colic it is, however, firmly retracted towards the spine, and the movements of the inflated intestines affected by spasmodic contraction, producing loud borborygmi, may frequently be seen and may be felt by the hand applied to the abdomen. The muscles of the abdominal wall and the bladder usually participate in the internal spasm: the abdomen becomes rigid or knotted, and the recti muscles become contracted into round balls, while frequently the navel is retracted, micturition is frequent or suppressed. Usually there is constipation, and the pain disappears when the bowels are freely relieved; sometimes, however, it persists for a time. Constipation stands in a twofold relation to colic, either as cause or effect of the spasm.

The countenance expresses great suffering, anxiety, and depression, and the features may be pinched. The surface of the body is cold, especially the feet, and the pale skin is covered by a cold perspiration. The pulse is commonly of normal frequency, or is infrequent and feeble.

The symptoms vary somewhat with the cause. When due to irritating ingesta the prominent symptoms are vomiting and diarrhoea, sometimes ending in catarrhal dysentery. In children the legs are drawn up upon the abdomen, the bowels are often at first confined, and the evacuations greenish, offensive, and very acid, afterwards becoming loose.

In nervous and hypochondriacal subjects, and especially females, severe pain in the intestines, resembling that of spasmodic colic, is apt to occur (*see ENTERALGIA*). Flatulence plays a varying part in different cases; it is often a prominent symptom, and the form of colic thus characterised has been termed *Colica flatulenta*.

Vomiting is generally in proportion to the severeness of spasm, and the degree of intestinal obstruction.

DURATION.—The duration of the attack varies greatly, from a few minutes to several days. The spasm usually ceases abruptly, leaving a feeling of

soreness in the abdomen, while there is enjoyable relief from suffering. Colic, when violent or intractable, may terminate in enteritis, in peritonitis, and, especially in children, in intussusception.

DIAGNOSIS.—A pain moving from place to place, relieved by firm pressure and unattended by fever, separates colic from other affections, more particularly from those due to inflammation, in which pain is always aggravated by pressure.

Distension with spasm of the stomach may be distinguished from a similar condition of the colon, by the pain occupying a higher position in the abdomen (at or around the ensiform cartilage instead of—as in colic—the umbilical or hypochondriac regions), and by the percussion note elicited being deeper-toned and more prolonged than that which is produced by a distended colon; besides in colic the spasmodic contraction of the colon, producing borborygmi, may be tried by the hand, or may be even seen, and there is tenismus.

It should be borne in mind that enteritis or peritonitis may follow colic, when the pulse, previously unaltered, may become frequent, hard and small, or frequent and soft, and the seat of inflammation becomes tender.

PROGNOSIS.—Colic almost always ends in recovery, preceded by free evacuation from the bowels. Unfavourable signs are those arising from inflammation or intestinal obstruction.

TREATMENT.—In the first place the ætiological indications should be met. The irritating contents of the bowels should be dislodged by purgatives combined with sedatives, such as calomel (five or eight grains) or rhubarb (twenty grains) with opium (one grain), followed by repeated doses of some saline aperient, such as magnesiae vel potassae sulph., with tinct. of henbane or opium, and spirits of chloroform, until free action of the bowels is obtained.

A suppository containing half a grain each of hydrochlorate of morphia and extract of belladonna, or a subcutaneous injection of morphia, may secure immediate relief from pain before aperients have time to act. Large warm enemata often relieve quickly. Other suitable measures are—the warm bath, friction with warm oil or stimulating liniments, hot-water fomentations, steamed flannels, mustard or turpentine stupes, flannel bags containing hot chamomile flowers or heated sand, the stomach-warmer filled with hot water, large linseed and mustard poultice. The diet should be liquid.

In the prophylactic treatment the diet should be strictly regulated, lodgment of irritating solids and gases within the bowels should be prevented (*see CONSTIPATION; FÆCUS, Retention of; and FLATULENCE*), and the abdomen and feet should be kept warm by a flannel roller or belt and thick woollen stockings. *GIORGE OLIVER.*

COLLAPSE.—**DEFINITION.**—Collapse is a state of nervous prostration. When it is extreme, the vital functions are in a condition of partial, and sometimes nearly complete, abeyance. It may terminate in death, or be followed by gradual reaction and complete recovery.

Collapse and shock have usually been classed together, but it is not accurate to do so. It is

true that the ganglionic centres of the medulla oblongata are more or less profoundly involved in both, and that both possess many symptoms in common, dependent upon the derangement of function of one or more of these centres. Some confusion is attributable to the fact that shock is a term applied not only to a state or morbid condition, but to the cause which most frequently produces that condition—a violent impression or 'shock' to the nervous centres. *See SHOCK.* Collapse arises from many different causes, shock being one, of which collapse may be regarded as a final and extreme degree, and into which it often imperceptibly passes. Collapse, on the other hand, may occur under conditions where there has been no antecedent state of shock. Collapse presupposes previous nervous exhaustion, while shock may instantly appear in a healthy individual.

ÆTIOLOGY.—Any severe injury, especially if attended by profuse and sudden hæmorrhage, may terminate in collapse, such, for instance, as the rupture of one of the abdominal viscera, a penetrating wound of the chest or abdomen, or a wound of the heart or of a large artery. Extensive burns or scalds frequently give rise to typical collapse; and severe and prolonged pain is capable of causing it. Rupture of the heart or of an internal aneurism, if the patient do not immediately die, causes extreme collapse. Certain poisons, as tobacco and arsenic, will also produce this condition. It is the terminal stage of some diseases, as, for instance, of Asiatic cholera; severe drastic purgation also, or prolonged vomiting, from whatever cause may occasion it. The pernicious malarious fevers and yellow fever often end in collapse. In the acute yellow atrophy of the liver symptoms of severe nervous disturbance, resulting in a species of collapse, sometimes suddenly supervene. Pyæmia, septicæmia, prolonged narcosis, frequently terminate in collapse.

SYMPTOMS.—The severity of collapse depends on the nature of the cause and the physical and mental vigour of the individual. It may vary from a moderate to an extreme degree. A moderate amount is seen in the course of fever and some other diseases, but this neither modifies the progress of the malady nor attracts the notice of the patient, causing chiefly peripheral coldness. From this trifling amount collapse may pass to the most intense form, where the patient scarcely differs in outward semblance from a dead body. A superficial inspection will fail to detect the existence of the functions of respiration and circulation. Vitality may be said to have reached its minimum. In well-marked collapse from severe injury or loss of blood the pulse at the wrist may be almost or wholly imperceptible, the heart's action scarcely audible, very rapid, fluttering, and irregular; the surface of the body, the face especially, is deadly pale and cold, and the skin moist with clammy sweat; the respiration is very feeble, slow, and irregular, accompanied by sighing or gasping inspirations at intervals, the expression and character of the face are lost; the features are sunken and relaxed; the eye is dull, glassy, staring, or languidly rolling about, and the conjunctiva perhaps insensible to the touch; the nostrils are dilated; the sensibility

of the whole body is diminished; and the muscular debility is extreme. The patient lies on his back, without a trace of voluntary effort. If a limb is lifted it falls back again as if dead. Yet the consciousness and senses may be almost unimpaired; if roused by repeated questions the sufferer will with visible effort make a coherent though, probably, inadequate reply.

If relief be not given, the respiration may become slower and slower till each one appears the last, when a sudden sigh shows that life is still present; finally, the pulse and heart's action become more and more faint, and death results from pure asthenia. A condition closely resembling traumatic collapse is often witnessed in the last stage of cholera, when in an extreme degree the patient almost resembles a corpse save for the convulsive motions induced from time to time by the painful cramps. The surface is pale or bluish, covered with profuse sweat, but is at the same time cold to the touch. The hands and extremities are icy cold, the tongue is cold, and so also is the breath, which is gasping and paroxysmal; no pulse can be felt at the wrist; the eyes and features are sunken; the mind is apathetic, but nevertheless the consciousness may be perfect, and the patient able to respond to questions with a strong voice. Severe purging and tobacco-poisoning produce a condition extremely like that described as traumatic collapse.

Some cases of malignant fever terminate in collapse, which is characterised by extreme anxiety, pallor or lividity of the face and surface, coldness of the skin, sweating, and a small, frequent, and irregular pulse.

A decrease of animal heat, especially in the external parts, is characteristic of collapse. The temperature of the internal organs varies; and there may be collapse with high internal temperature. This occurs in cholera, intense fevers, and some forms of septicæmia; or the converse may obtain, as is frequently witnessed in the collapse of dissolution. Collapse from loss of blood differs from syncope, although the latter may be described as an acute and transient form of collapse. In syncope the prominent symptom is loss of consciousness, which in collapse may be almost or quite perfect.

For the PATHOLOGY and TREATMENT of collapse see SHOCK. WILLIAM MACCORMAC.

COLLAPSE, Pulmonary.—A condition in which the lung is simply more or less devoid of air. *See LUNG, Collapse of.*

COLLIQUATIVE (*colliqueo*, I melt).—A term which originated in the belief that in certain conditions the solid parts melted away, and were carried off as *liquid* discharges. The word is now generally applied to the copious sweats and diarrhoea which occur in certain wasting diseases, such as phthisis.

COLLOID (*κόλλα*, glue, and *ειδος*, like).—A peculiar morbid product resembling in its characters glue or jelly, and found associated with cancer and other forms of new-growth. *See CANCER and DEGENERATION.*

COLON, Diseases of.—The colon participates to a varying extent in the lesions and

derangements of dysentery, typhoid fever, enteritis, peritonitis, and other affections. The special disorders to which it is most liable are intimately connected with its anatomical and physiological peculiarities. The colon is a distensible membranous tube, of large capacity, with chiefly solid contents, which are propelled slowly onwards by the muscular contractions of the walls. The moving force and the resistance offered to it are often too finely balanced, so that whenever the energy of the former is somewhat reduced, an accumulation of excretory products is apt to be determined. Hence arise retention of feces and gases, constipation and consecutive evils, such as colic, colo-enteritis, or ulceration of the colon.

I. Atony.—**Definition.**—Loss of contractility of the walls of the colon, leading to accumulations and other sequelae.

Ætiology.—The causes of torpor or atony of the colon are mainly those of constipation—sedentaryness, indolent and luxurious habits, a sluggish and lymphatic temperament, old age, and general debility or exhaustion, as after a long and tedious illness. Whenever the walls of the colon are distended by solid or gaseous accumulations, the contractile power is apt to be enfeebled, leading to further retention and loss of tone.

Atony of the colon is an essential element in the pathogeny of constipation not depending on mechanical obstruction. Tympanitic distension of the colon from paralysis of the sympathetic nerve occurs in peritonitis and in fevers, e.g. typhus fever.

Symptoms.—Torpor of the colon may be indicated only by constipation. There are usually the ordinary signs of retention of flatus or feces. In hysteria, and in inflammation of the bowels or peritoneum, flatus is apt to accumulate rapidly, and to produce great distension of the colon. Fæces may collect and form large tumours in any part of the large intestines, but especially in the cæcum and sigmoid flexure.

Fæcal and gaseous accumulations in the colon resulting from atony may produce the following effects, directly or remotely connected with them.—

(a.) *Local.*—1, Colic. 2, Inflammation of the walls of the colon, or of the mucous and submucous coats, and ulceration. 3, Disturbances from pressure: thus flatulent distension, and large fæcal accumulation encroaching on the cavity of the thorax and impeding the descent of the diaphragm, may cause dyspnoea or short and rapid respiration, palpitation and irregular action of the heart, with remote effects arising from a disturbed circulation in the brain, such as giddiness and headache; a distended cæcum or sigmoid flexure pressing on veins and nerves may induce œdema, numbness, and cramps of the right or left lower extremity. 4, Retarded digestion, derangement of the stomach and liver, and intestinal obstruction.

(b.) *General.*—The absorption of excrementitious matter is said to lead to wide-spread general effects, such as a sallow earthy, or dirty complexion, lassitude, debility, offensive breath, loaded urine, &c.

Treatment.—Atony of the colon is usually a chronic disorder demanding prolonged treatment.

The hygienic and dietetic rules laid down in the article CONSTIPATION require in most cases to be supplemented by medicines. The most satisfactory results follow a course of tonics, combined with aperients, such as iron, quinine, strychnia, belladonna, with aloes, colocynth, or rhubarb.

The purgative should be adjusted to each case, so as to secure no more and no less than a regular and efficient evacuation; and while the loaded colon continues to be thus relieved, the dose should be very gradually reduced.

This tonic-aperient course may be greatly aided by local stimulation of the colon, as by friction, kneading, electricity, cold-water compresses, or douches. The abdomen should be supported by a belt or roller. Bretteau and Trouseau strongly advised a course of belladonna, giving gr. $\frac{1}{4}$ of the extract or of the powdered leaf as a pill in the early morning,—the stomach being empty,—then two such pills in four or five days the bowels do not respond, and increasing the dose, but not beyond that contained in four or five pills, in twenty-four hours. A teaspoonful of castor oil may be given twice a week to aid this course of treatment. Flatulent distension of the colon in the elderly and in females at the climacteric period is often greatly relieved by the prolonged use of a pill containing compound assafœtida pill and nuxvomica after meals. Electricity is sometimes used with benefit.

Tympanitic distension of the colon in peritonitis and in fevers is best treated by free doses of opium.

II Inflammation.—**Synon.** Colitis, colonitis, colo-enteritis, Fr. *colite*, Ger. *Entzündung des Schleimhauts des Kolons*.

An inflammation with ulceration of the mucous membrane and submucous connective tissue of the colon, producing lesions undistinguishable from those of dysentery, has been pointed out by Copland and Parkes. Colitis is said to be a non-specific local affection, commencing in the submucous tissue, and subsequently attacking the mucous membrane with its glandular structures—the primary seat of dysenteric inflammation. As in dysentery the inflammation induces gangrenous destruction and ulceration of the mucous membrane and underlying cellular tissue.

A *catarrhal* form of colitis is apt to occur in measles. 'It often happens that the morbillous catarrh of the intestines exhausts itself by attacking the large intestine, producing that special form of colitis characterised by tenesmus and glairy bloody stools.' Inflammatory diarrhoea, particularly in children, often terminates similarly.

Colitis arising from retained *æcoria* may involve the entire wall of a circumscribed portion of the colon, commonly the ascending colon and sigmoid flexure, or may be confined to the mucous and submucous tissues. In inflammation of the cæcum (typhilitis) the walls of the ascending colon are more or less implicated. In fæcal retention the mucous follicles of the colon may become obstructed, and the distension resulting therefrom may lead to inflammation and ulceration. Irritation of the mucous lining of the colon from the lodgment of feces may extend to the lymphatic vessels and glands. The glan-

¹ Trouseau, *Clinique Médecinale*.

dular enlargement cannot, however, usually be recognised during life. While the symptoms of *tubercles mesenterici* may be traced to enlargement and obstruction of the mesenteric glands, set up by irritation of the intestinal tract, it is doubtful whether such results can follow a similar cause limited to the colon only.

TREATMENT.—The treatment of colitis consists in the local application of fomentations, poultices, opium enemata, or morphia suppositories, and in the use of gentle laxatives, such as castor oil, combined with sedatives, such as opium or henbane. The catarrhal form generally terminates in spontaneous recovery. Trousseau advises the use of albuminous injections, or of injections containing about half an ounce of water and nitrate of silver—from $\frac{1}{2}$ to $1\frac{1}{4}$ grains,—or sulphate of copper or sulphate of zinc—from $3\frac{1}{4}$ to $4\frac{1}{2}$ grains.

III. Displacements.—The parts of the colon most liable to displacement are the transverse colon and sigmoid flexure—the former may descend as low as the pubes, and the latter may occupy any position between the left iliac region and the right side of the abdomen. Usually the meso-colon is elongated; there is adhesion between the displaced part and the new site, and, the longitudinal bands being elongated, the loculi are obliterated. Displacements are most apt to occur in those who have long suffered from constipation, retention of feces, chronic dysentery, hernia, or from encysted or other tumours. They may lead to complete obstruction, and cannot usually be recognised with certainty during life.

IV. Diverticula.—A loculus of the colon from repeated accumulation may become so distended as to form a lateral appendix. Such a diverticulum when loaded with feces may be felt through the abdominal wall as a distinct tumour, which may collapse when pressed between the fingers.

COLOUR-BLINDNESS.—A defect of vision, the subject of which is unable to distinguish certain colours. See VISION, Disorders of.

COMA (*κῆμα*, deep sleep).—A condition of profound insensibility. See CONSCIOUSNESS, Disorders of.

COMA-VIGIL (*κῆμα*, insensibility, and *vigil*, wakeful).

DEFINITION.—A symptom, or set of symptoms, where continuous sleeplessness is associated with partial unconsciousness.

Coma-vigil occurs towards the end of diseases in which the nervous system is involved either directly or indirectly, especially where sleeplessness has been a symptom in the earlier part of the disease. Thus it frequently appears towards the end of an attack of typhus or of delirium tremens, when these are about to terminate fatally.

SYMPTOMS.—The patient lies quiet with his eyes half-closed, inattentive to everything around, but not absolutely unconscious. If the eyelids are touched, they are closed, and perhaps the head is slowly turned away. The eyes have a dull, half-glazed look, and slowly follow any moving object near them. The pupils are neither much dilated nor contracted and they

more under the influence of light, but very sluggishly. The mouth is generally somewhat open and dry, as are also the lips. The power of swallowing is much impaired; if a small quantity of fluid be put into the mouth, an effort is made after a short time to swallow it, and this effort is for a time successful; but after the symptoms have been present for some time, the effort is so feeble that no result follows. The patient lies mostly on the back; if turned on the side, he either remains as placed, or often slowly turns to the former position on the back. The limbs are occasionally moved a little, and if the hand or arm be raised, a slight resistance is offered. If the bladder or the rectum be emptied, there is slight consciousness of the act, as if a feeling of discomfort preceded it. The pulse is quick and weak. The respiration is weak, but otherwise normal. The symptoms continue unbroken throughout, nothing like natural sleep occurring.

DIAGNOSIS.—Coma-vigil is distinguished from coma by the presence of a certain amount of consciousness, by the quick pulse, and by the absence of stertorous breathing. It is distinguished from concussion of the brain by the pupil not being contracted, by the history of the case, and by the absence of coldness of the skin, and of any sign of shock.

PROGNOSIS.—The prognosis is unfavourable; coma-vigil is almost invariably a fatal symptom. It may last from a few hours to three or four days; from twenty-four to forty-eight hours being the most common duration. It may deepen into actual coma; but more usually the symptoms change but little, save that the pulse becomes quicker and weaker, and the respiration more feeble, and death by asthenia then results.

PATHOLOGY.—As being little but a symptom, coma-vigil has strictly speaking no pathology. It seems to coincide with the gradual suspension through exhaustion of the functions of the nervous centres; the cerebral hemispheres being nearly if not quite inactive, while the action of the rest of the centres is kept up weakly but continuously, till the little remaining nervous power is exhausted, when death ensues. It differs from coma, inasmuch as in the latter, the medulla oblongata is the only centre left active, the functions of the rest being entirely suspended. It differs from concussion, inasmuch as the symptoms attending the temporary unconsciousness of the latter are more those of irritation than of pure suspension of function. R. BUCHANAN.

COMEDONES (*comedo*, I consume).—**SYNON :** Grubs.—This is the name applied to the little cylinders of sebaceous and epithelial substance which are apt to accumulate in the follicles of the skin, and to appear on the surface as small round black spots. When squeezed out they have the appearance of minute maggots or grubs with black heads, and thence have derived their name. They may occur in all parts of the body where sebaceous follicles exist, but are most common on the face, the nose, the neck and shoulders, the breast, and within the concha of the ears, in the latter situation often attaining a considerable size. The accumulation of this substance is due to want of

expulsive power of the skin, and to the slight impediment which is afforded by the aperture of the follicle to its exit; and when squeezed out it is found to vary in colour, in figure, and in density, according to the period of its detention. When recent, the comedones are soft and white, and modelled into an exact cylinder by compression through the mouth of the follicle; when impacted for a considerable time they acquire the yellow tinge, the transparency and hardness of horn; and assume a bulbous figure from the dilatation of the follicle below the constricted orifice of the epidermis; and by their bulk they sometimes stretch the hair-follicle so far as to obliterate it completely. Besides their usual composition of sebaceous substance and epithelial cells, they frequently contain lanuginous hairs, and not rarely the entozoon folliculorum in its different phases of development. When they raise the pore into a minute pimple they have a similitude to *acne punctata*, and might be mistaken for that affection; whilst the black spot on the summit of comedo is due to a comedo.

TREATMENT.—Comedones are generally associated with a weak state of the skin as well as of the individual; they are most frequently met with in young persons in whom the powers of the constitution are not yet established, and will be benefited by generous diet and tonic treatment. Locally, soap and water with plentiful friction and ablution will be found of great service; and, as an astringent to invigorate a debilitated skin, a lotion of perchloride of mercury, in emulsion of bitter almonds (two grains to an ounce) and spirits of wine.

ERASMUS WILSON.

COMPLICATION (*con*, with, and *pluco*, I fold).—It is difficult to give a strict definition of what ought to be included under the term *complication*, but the word signifies the occurrence during the course of a disease of some other affection, or of some symptom or group of symptoms not usually observed, by which its progress is therefore complicated, and not uncommonly more or less seriously modified. The difficulty lies in determining what should be looked upon as essentially part of the original disease, and what as a mere accidental occurrence. For instance, many regard the cardiac affections which so often arise during the progress of acute rheumatism as a part of the complaint, others as complications. The same remark applies to the relationship of renal disease to scarlatina, as well as to numerous other cases.

Complications arise in different ways. They may, as just indicated, be considered as developments of the original morbid condition, resulting from the same cause and being more or less allied; or they are independent and accidental, of which an illustration is to be found in the association of ague with scurvy or dysentery, or in the co-existence of two or more of the exanthemata. The most important class of complications, however, are those which follow the primary disease as more or less direct consequences. These may further be induced in various ways. Thus, for example, in febrile diseases secondary lesions are liable to arise as

a result of changes in the blood; a mechanical act, such as cough, may lead to complications in the course of phthisis and other pulmonary affections; cardiac diseases frequently bring about consecutive changes in other organs, by inducing obstruction of the venous circulation, or emboli may originate under certain conditions and produce their usual consequences. It is of great practical importance to be acquainted with the complications which are liable to be met with in the various diseases, and especially in those which are of an acute nature, in order that measures may be taken to prevent them, and that they may be recognized and treated at the earliest possible period, if they should occur.

FREDERICK T. ROBERTS.

COMPOUND GRANULAR CORPUSCLES.—Formerly these microscopic objects were regarded as of inflammatory origin, and as affording positive evidence of the occurrence of inflammation. Hence they were termed 'compound inflammation globules' (Glaize). Almost all pathologists now, however, recognize the fact that they are not products of an inflammatory process, but result either from the degeneration of pre-existing cells, in which protein and fatty granules accumulate, or, perhaps, from the aggregation of granules originally distinct, which are present in abundance in degenerating tissues. They may even be formed out of the cells of morbid products, such as cancer. These compound granular corpuscles derive their name from the fact that they consist of a large number of minute granules aggregated together, and they either present a delicate cell-wall, or this cannot be detected. Occasionally there is an appearance of a nucleus in the centre.

FREDERICK T. ROBERTS.

COMPRESS.—Folds of lint or other material, which are used for the purpose of producing pressure, or as a pad by which hot or cold water or medicinal agents may be applied to the surface. In the latter case the compress may be rendered waterproof by being covered by a piece of gutta-percha tissue or mackintosh-cloth. *See* HYDROPATHY.

COMPRESSIBLE.—A term implying comparatively slight resistance, and applied specially to the pulse when it yields readily under the finger. *See* PULSE, The.

COMPRESSION of Brain. *See* BRAIN, Compression of.

COMPRESSION of Lung. *See* LUNG, Compression of.

CONCRETION (*con*, together, and *creasco*, I grow).—SYNON.: Calculus; *Fr.* *Concrétion*, *Calcul*; *Ger.* *Concrement*.

DEFINITION.—An unorganised body, formed either in one of the natural cavities or canals, or in the substance of an organ, by the deposit of certain solid constituents of the fluids of the part. In the widest sense of the term, Concretions comprehend Calculi.

ENUMERATION and CLASSIFICATION.—The following classified list includes the principal varieties of concretions:—

1. In *glandular structures*: *lactearial*, *sali-*

vary, pancreatic, prostatic, seminal, urinary, hepatic, sebaceous, and mammary.

2. In the *circulatory system*: cardiac, and venous (*phlebotitis*).

3. In *closed sacs*: peritoneal, and articular.

4. In *ouls-de-sac*: bronchial, pulmonary, nasal, tonsillar, laryngeal, gastric, intestinal, præputial, uterine, and vaginal.

5. In the *substances of tissues* and new formations, especially in the nervous system—*Corpora amylacea*.

6. *Varicous*, such as the concretions on the teeth known as *tartar*.

GENERAL CHARACTERS AND NUMBER.—Concretions are generally firm or even of stony hardness; but they may be soft and friable. Their colour varies from white to black through shades of yellow and red. Concretions occur either singly or in groups; and their shape and size, as well as the character of their surface, vary considerably with their number; single concretions being more frequently rounded, larger, and less smooth than multiple specimens, which often present facets and polished surfaces. Many concretions are composed of concentric laminae.

COMPOSITION.—The chief constituents of concretions are inorganic, that is, mineral salts, in a basis of organic matter. The bulk of the salts are carbonate and phosphate of lime and magnesia, with smaller quantities of alkaline compounds. The organic basis is composed of albuminous substances, mucus, cholesterol, and colouring matters.

Modes of FORMATION.—Concretions are generally derived from the solid constituents of vital fluids, whether physiological or pathological. In most instances the fluids are delayed in the natural passages by some abnormal obstruction or dilatation; and under such circumstances a chronic inflammatory condition of the walls contributes greatly to the probability of mineral deposit. Most frequently—as in the formation of the salivary and biliary concretions—the fluid portions of the secretion escape by the natural outlet or are absorbed, while the solid constituents are deposited; the particles being either agglomerated around a nucleus, or deposited in centripetal layers upon the surface of the cavity. In other instances—intracardiac, peritoneal, and articular, a nucleus is furnished by a portion of fibrin, blood-clot, or growth, on which fresh deposits take place, while calcification proceeds in the interior. In a third series, examples of which are found in the alimentary canal, the basis of the concretion consists of foreign or indigestible matter, such as hair, inspissated feces, and masses of magnesia.

EFFECTS AND SYMPTOMS.—The functions of a part occupied by a concretion are generally more or less impaired; the neighbouring tissues frequently atrophy; and inflammation and ulceration are common results, ending probably in the escape of the body. The concretion may be passed along a duct, and this process is generally attended with great pain; but concretions may remain where formed without causing symptoms. Occasionally they are spontaneously disintegrated or dissolved.

TREATMENT.—The treatment of concretions will

be found discussed under the heads of the diseases of the organs where they respectively occur.

J. MITCHELL BRUCE.

CONCUSSION (*concussio*, I shake together).

This term is used to indicate a condition induced by a more or less violent shaking or physical commotion of the general system, or of some particular organ, whereby serious symptoms may be induced, but no definite lesion can be detected to account for them. The nerve-centres are the parts most liable to be thus affected, concussion of the brain or spinal cord being of considerable moment, giving rise to more or less complete abolition of their functions, though this effect is usually only temporary. See BRAIN, and SPINAL CORD, Concussion of. General concussion of the body is highly important at the present day, in connexion with railway accidents, after which persons seem to be uninjured, or only to be slightly shaken, but subsequently grave symptoms, associated with the nervous system, set in. See RAILWAY ACCIDENTS, Results of.

FREDERICK T. ROBERTS.

CONCUSSION OF BRAIN, SPINE, &c. See BRAIN; and SPINAL CORD, Diseases of.

CONDYLOMA (Lat).—**DEFINITION.**—Excrecences often found about the anus and organs of generation in both sexes. The term has been applied to simple cutaneous growths as well as to those of syphilitic origin; but since these latter are altogether due to a constitutional taint, and require a different treatment, they will be described separately under the heading of *MICROCUTANEOUS*, whilst the term *Condyloma* will be restricted to non-specific growths.

SYMPTOMS.—Condylomata are generally situated in the neighbourhood of the anus and genital organs; and they result from the irritation produced by acrid vaginal or rectal discharges, or by the natural secretions in dirty persons. They consist in hypertrophy of the tegumentary tissues, and generally form smooth pendulous growths, but they may be flattened, irregular, and ulcerated on the surface. They are vascular, liable to become inflamed and painful from friction, and, as their position favours development, they may attain considerable size.

TREATMENT.—When all inflammation has been allayed, these excrecences should be removed with a pair of scissors; and to prevent their recurrence thorough cleanliness must be practised, and any discharge from the rectum or vagina stopped. If the parts be damp and perspiring they should be kept dry, and frequently dusted with zinc or bismuth powder, or bathed with some astringent lotion. No general treatment is of the slightest service.

GEORGE G. GASCOTT.

CONFLUENT (*confluo*, I run together).—Applied chiefly to a variety of smallpox and of other exanthemata, in which the eruption runs together or coalesces.

CONGENITAL (*con*, together, and *genitus*, begotten).—Existing at birth: a term generally applied to diseases or malformations, such as *Congenital Syphilis*, and *Congenital Clubfoot*.

CONGESTION (*congero, I accumulate*).—Overfulness of vessels caused by accumulation of their contents: generally applied to blood-vessels. See CIRCULATION, Disorders of.

CONIUM, Poisoning by. See APPENDIX.

CONJUNCTIVITIS.—Inflammation of the conjunctiva. See EYE AND ITS APPENDAGES, Diseases of.

CONSCIOUSNESS, Disorders of.—The disorders of consciousness are so numerous as to make it desirable briefly to consider them in one article, with a view to their classification and the better comprehension of their mutual relations. We shall, therefore, here group and arrange the various morbid conscious states, not aiming to produce a strictly scientific classification so much as one which will be practically useful.

1. **Exaltation of.**—Under this head may be ranged certain states of consciousness more or less distinctly bordering upon the unnatural, to be met with in persons under the influence of 'mental excitement' from various causes, as from sudden good news, or generally pleasant surroundings; also from a slight degree of poisoning by alcohol, opium, hashish, or other drugs; or from an early stage of some forms of insanity, or of delirium. In this state of mental exaltation the individual's powers of perception, apprehension, recollection, thought, emotion, and volition, would seem to be all more or less intensified, just as in that of hebetude or dementia they are diminished and consciousness is proportionately dwarfed.

2. **Perversions of.**—Many of the various defects here to be referred to are very partial in the extent to which they implicate consciousness, though others are general. In what is known as an *illusion* some object of sense is not correctly perceived; or, in other words, some sensorial impression is quite wrongly interpreted, as when a feverish or a maniacal patient, looking at some inanimate object, declares that it is a cat or a dog about to fly at him, or hearing even the slightest noise in any part of his room, interprets it to be the voice of some friend or imagined enemy. In the case of an *hallucination*, however, forms are declared to be seen, or voices heard (by a patient suffering from delirium tremens, for instance), where no appreciable external realities could have started the notion. And in these cases, it is not that the patient sees or hears without believing; he implicitly believes that the visions or voices which have been conjured up subjectively by the working of his own brain, have a real existence in the outside world. It is necessary to make this distinction because it is by no means uncommon in regard to the olfactory sense (especially in some epileptics), for odours or smells to be perceived which the patient soon comes to know are purely subjective or devoid of any external correlative.

Hallucinations and illusions, though occasionally existing alone, are quite commonly associated with a very important and more general derangement of consciousness, viz., *delirium*. This is a symptom very common in many

fevers, in certain low states of the system, after severe frights, in inflammatory or other lesions of the brain and its membranes, as a result of some narcotico-irritant poison, or occasionally in a person who is recovering from an epileptic attack, or from the stupor sequential to a series of convulsive attacks. The state itself varies much in intensity. Three fairly distinct types exist. In (a) *low or muttering delirium* the patient lies still and more or less heedless of what is occurring around; or if heeding at all, the impressions which he receives give rise to erroneous perceptions (illusions) which are woven into the incoherent fabric of his rambling thought. In (b) *delirium tremens* the patient is more restless, tremors of the limbs and of the muscles of the face are often easily induced, hallucinations of sight and hearing are common, and the character of the delirium reveals that the patient is, to an unusual extent, possessed by fears, terrors, and other emotions of a depressing type. In (c) *wild or raving delirium* we have to do with a much more active state. The patient raves loudly and incoherently, more in regard to his fleeting dream-like thoughts than in connection with external impressions, of which he is more or less heedless. He is often violent in demeanour, and difficult to be restrained, persons in this state being capable of great and prolonged muscular exertion. The bodily activity accompanying this form of delirium is, in fact, just as characteristic as the great intensity of the mental processes. It is met with occasionally in some fevers, but more commonly in meningitis and in acute mania.

In its early stages delirium is principally noticed during the transition-period between waking and sleeping—at times, that is, when the nervous system most needs the reinvigorating influence of sleep. It is in these cases, too, that beef-tea or stimulants may for a time dispel all traces of the wandering thought. Whilst illusions and hallucinations enter largely into the mental activity of a delirious patient, *delusions* also are generally well-marked components. That is to say, the person becomes for a time possessed by an idea, notion, or fancy, for which there is no real warranty, though he believes and wishes to act as though it were true.

Somewhat allied to delirium in nature, though much lower in intensity as a mental process, is that *incoherence* of thought which is met with in many chronic maniacs, or in non-febrile patients suffering from various organic brain-diseases. In its slighter degrees this incoherence displays itself as mere 'rambling' talk; the patient has not sufficient brain-power to follow up the main subject of thought, and is frequently diverted into collateral channels. This, which is a natural state with some persons, may be distinctly indicative of disease in others whose mental power has previously been of a more vigorous type. At times the incoherence is seen to be governed principally by mere verbal suggestion, the patient being led away from point to point in new directions, owing to the associations of some word which has been used becoming for the time dominant. This state is often well seen in the sub-acute exacerbations of

chloric mania, though it may occur also where multiple softening or indurations of the brain exist. At other times the incoherence is more absolute—wayward transitions from subject to subject, connected by no discoverable bond, rapidly following one another. The result in such a case is a mere unmeaning jumble of words, interspersed here and there with brief propositions having a limited significance of their own, though often wholly unrelated to that which precedes or follows.

Hypochondriasis is a perverted state of consciousness, having some resemblance to that of illusion, but in which some internal or visceral state becomes the starting-point of impressions (possibly not actually painful) which, when magnified and perverted as they are in the mind of the patient, fill him with false and gloomy apprehensions of various kinds. This perversion of consciousness is more generalised than that which exists in the case of illusion; and also instead of being a more or less temporary defect, it is one that may last for weeks, months, or even years. The state of mind of an hysterical patient is often not altogether different from that of the hypochondriac.

3. *Partial Loss of*—Defects of this order are numerous and may exist in great variety. They may implicate almost equally nearly all the varieties of conscious mental activity, or some more than others. They may be either congenital, or acquired during the life of the individual.

In *idiocy* we may have from birth defect in the power of concentrating the attention, a defective power of apprehension and of thinking, and a defective volition, shown alike by an inability to guide or control thought, and by a deficient vigour of bodily movement. Again, as a result of epilepsy, of organic brain-disease, or of injuries to the head, the patient may gradually lapse into such a condition from one of health, so as to become, as it is termed, 'demented.' Whilst this state of *dementia* may supervene at any age, it is much more common as a consequence of the brain-diseases frequent in advanced life. There is, moreover, a form known as *senile dementia*, in which without any typical disease, but as a consequence of impaired tissue-vitality and diffused degenerative changes throughout the nervous system, the mental faculties undergo a more marked degradation than is usually met with in old age. This condition in its minor degrees goes by the name of *hebetude*. In all such states or grades of idiocy and dementia, we meet with an undue tendency to sleep in the day-time as a result of the listless and languid mental condition. This is but another sign of the general lowering of conscious vigour.

Here we must include, also, a peculiar group of conditions, having some alliance to one another, and which are all characterised by loss of consciousness to some extent, either partial in range or general. They are—*reverie*, *somnambulism*, *ecstasy*, *coma-vigil*, *cataplexy*, *hypnotism*, and *trance*. They are merely enumerated here, but are defined or described in their several places. In the latter of these conditions the loss of consciousness, in the ordinary acceptance of

the term (*viz.* loss of perceptive power) is so absolute, that some may think it ought rather to be included in the next section. Loss of perceptive power, however, would not seem to be absolutely synonymous with loss of consciousness. There is good reason to believe, for instance, that where the influence of chloroform and other anaesthetics is not pushed to the fullest extent, a condition of *anaesthesia* intermediate between slight and profound is produced, in which, whilst there is absolutely no consciousness for external impressions, so that pain is altogether unfelt, there is still a certain amount of cerebral activity—as evidenced by rambling and indistinct speech on subjects altogether apart from what the surgeon may be doing. There is mental activity clearly, though the nature of this, as revealed by the patient's speech, may preclude the notion that pain is at the time being felt. Sensorial consciousness is blotted out, whilst a kind of ideational consciousness remains. We have an approximation to such a condition, also, in the case of *sleep* when dreams are rife. But here sensorial consciousness is not completely in abeyance. Again, in certain rare and anomalous epileptiform attacks we may find the patients, after the first paroxysms, bereft of some senses, though not of others. They may hear what is said by those around them, though they continue for a time quite unable to see or speak.

4. *Complete Loss of*.—In very profound sleep (*sopor*), in that prolonged form of it in which the person, if he can be momentarily roused, drops off again immediately (*lethargy*), and also in profound *anaesthesia*, there is complete loss of consciousness. The terms *sopor* and *lethargy* are now rarely used, and authors are not even agreed as to the precise state which should be designated by the latter word.

In *syncope* we have insensibility resulting from a cutting off of the proper supply of blood to the brain, whilst in *apoplexy* we have a like result following upon an interference with respiration.

A condition of *narcosis* or profound insensibility may result from opium or other drugs and poisons, amongst which alcohol is to be included as one of the most common producers of such a state. Or it may also be due to the deficient elimination of urinary products by the kidneys, when uræmic coma is produced.

Complete loss of consciousness exists for some time during the ordinary form of *epileptic fit*, or during an attack of convulsions; though in other epileptiform fits, not unfrequently met with—having some of the characters of hysterical convulsions—there seems to be a loss of sensorial consciousness only (loss of perception), whilst a certain amount of ideational consciousness remains. In *apoplexy* also there may be for hours or days a more or less profound loss of consciousness. In the less profound attacks, as well as after an epileptic fit or an attack of convulsions, the loss of consciousness is not complete, and we have a condition now commonly known as *stupor*. This state is also frequent as a result of concussion or other injuries of the brain, and it occasionally follows a severe fit of hysterical convulsions.

It may last for hours, days, or even weeks in some cases. In it the patient lies with his eyes closed, taking no heed of what is passing around, though he may show obvious signs of feeling when touched or pinched, and may be capable of being momentarily roused, so as to give a short monosyllabic answer, if slightly shaken or spoken to in a loud voice. On these occasions, signs of impatience are often shown. Though such a patient will not ask for food, he will often drink freely when it is offered. He will of his own accord, when his bladder is full, sometimes get out of bed, find the chamber-pot, use it, and return to bed without saying a word—and then speedily relapse into his previous state of stupor. When the insensibility is more profound, both urine and feces are passed incontinently.

The state just spoken of is referred to in this section because it is so intimately allied to and connected by all sorts of transition conditions with another, known as *coma*, in which the loss of consciousness is more complete and absolute. There are different degrees of stupor and there are different degrees of coma; the former is commonly spoken of as slight or deep, whilst a comatose condition, *coma*, and profound coma (the latter being what the older writers termed *carus*) are the phrases ordinarily used to denote the increasing insensibility of the graver state, which is more especially characteristic of the apoplectic condition. Coma may result from long-continued exposure to cold, from sun-stroke, from poisons of various kinds, from erysipelas of the head and face, from inflammations of the meninges, multiple embolisms, the effects of hyperpyrexia, or from cerebral hæmorrhage. The most common cause of very profound coma is cerebral hæmorrhage (apoplexy). In this condition the breathing is often loud and stertorous, and consciousness is entirely obliterated, so that there is an utter absence of reflex movements when a limb is pinched or when the conjunctiva is touched. The patient in the deeper forms of coma often cannot be roused at all, even for a moment, and if this state does not terminate in one way or another before the expiration of twenty-four hours, or if it does not gradually pass into one of mere stupor, a fatal result may be considered imminent.

H. CHARLTON BASTIAN.

CONSTIPATION (*con*, together, and *stipo*, I cram).—**DEFINITION**—Infrequent or incomplete alvine evacuation, leading to retention of feces.

ÆTIOLOGY—The causes of constipation may be *local*—an impediment to the onward movement of the feces in the large intestine or from the rectum; or *general*—pertaining to habits, diet, and other conditions.

Local.—These include:—(a) Lesions inducing narrowing of some part of the large intestine. (b) Collections of scybala, intestinal concretions, &c. in the cæcum, sigmoid flexure, or rectum. (c) Pressure on the rectum, by uterine fibroid or ovarian tumours, uterine displacement, the gravid uterus, or an enlarged prostate. (d) Defecation thwarted, as when the expiratory abdominal muscles are enfeebled, as in pregnancy, especially when repeated or after twins, obesity, old

age, or in some painful affection of the abdomen, such as rheumatism of the abdominal walls and diaphragm, chronic dysentery, piles, anal fissure.

(e) Feeble contraction of the intestinal muscular fibres, as in distension of the large intestine or a portion of it by gas, feces, or lumbrici, inflammatory affections, lead-poisoning, senile atrophy, or in delicate females with lax muscular fibres (see COLON, Diseases of). (f) Pain in the pelvic viscera and probably elsewhere may induce paralysis of the sympathetic nerves supplied to the intestinal walls, thus may be explained obstinate constipation in painful uterine and ovarian diseases, which cannot be accounted for by pressure on the bowels or otherwise.

General.—The general causes of constipation are:—(a) Sluggishness of function—lymphatic temperament, anemia, especially with amenorrhœa; or disposition to great activity of the muscular and nervous system. (b) Certain habits, namely, sedentariness; too great muscular activity, mental application, especially when excessive or prolonged; the continued use of aperients or enemata after the relief of temporary constipation; habitual disregard of, or hurry in the act of defecation; prolonged hours of sleep; the excessive or even moderate use of alcohol, tea, tobacco, or opium. (c) Dietetic errors.—Diet too nutritious—leaving little intestinal residue—or poor and insufficient; improper feeding, especially in infants and children; the use of indigestible substances, such as cheese, nuts, or cucumbers.

Constipation is frequently a prominent symptom in diseases of the stomach; of the liver; of the heart, inducing congestion of the portal system and of the nervous system; as well as in connexion with diabetes, excessive perspiration, prolonged lactation, and discharges.

The causes of constipation are such as evidently induce one or both of the following conditions.—1. Dryness and hardness of the contents of the large intestine from deficient secretion, or too active absorption of fluid from the intestinal tract. 2. Impaired contraction of the muscular fibres of the large intestine.

DESCRIPTION.—In constipation the evacuations are infrequent, solid, deficient in quantity, and sometimes unusually offensive; they often consist of dry, hard, dark or clay-coloured masses or scybala. Defecation is generally difficult or even painful. As a rule the depth of colour, and the scybala character of the motions, are in proportion to the duration of the lodgment of feces in the large intestine. Infrequency of defecation regarded alone is an untrustworthy sign of constipation, or constipation demanding medicinal or other treatment, inasmuch as it often depends on individual peculiarity. Good health is consistent with wide departures from the ordinary rule—a daily evacuation; not unfrequently there is no relief from the bowels for several days or even for a week, and yet without inconvenience, so long as the infrequent defecation is habitual, or can be ascribed to idiosyncrasy.

The disturbances of function usually associated with constipation may be local, or extend to distant parts.

The *immediate* or *local* effects are such as may arise from retention of feces:—*signa et sympto-*

collections in the cæcum, colon, sigmoid flexure, or rectum; irritation of portions of the intestine, indicated by colic, inflammation, ulceration, and perforation of the intestines; intestinal obstruction; pressure of fecal accumulations on the intra-pelvic vessels and nerves, inducing menorrhagia, uterine catarrh, seminal emissions, hemorrhoids, cold feet, neuralgia and numbness of the legs (Niemyer). Constipation frequently exerts a pernicious influence on primary digestion, indicated by foul tongue, fetid breath, anorexia, acidity, flatulence, biliary disturbance—even jaundice, and urine loaded with lithates.

The *remote or general* effects of constipation are lassitude of body and mind; headache, flushing and heat of head, vertigo; anemia and wasting.

TREATMENT.—Constipation depending on individual peculiarity is rarely relieved permanently by treatment. The bowels, having acquired from early life the habit of infrequent evacuation, may be stimulated for a time, and are then apt to become more sluggish than before. In all cases the habit of the patient in this respect from childhood should first be determined, either as a warning against active or prolonged treatment, which may prove injurious, or as a guide to the adjustment of directions and remedies—affording as it does a limit which should not be over-stepped.

1. *Ætiological, Dietetic, and Hygienic Treatment.*

—In treating constipation the causes should be met. Local causes—such as those inducing contraction of or pressure on some part of the large intestine, or feeble or ineffectual contraction of the intestinal muscular fibres or of the expiratory muscles, should first be eliminated. Habits disposing to constipation should also be corrected. Persons who are much preoccupied or careless are apt either to disregard the call to stool, or to perform the act of defecation hurriedly, incompletely, and at irregular intervals. The sensibility of the nerves of the rectum becomes blunted by the constant contact of feces. Hence the periodical removal of collections in the lower part of the large intestine is an essential element of the treatment. It is best when this can be done by well-timed natural efforts. The patient should be told to attempt defecation every day after breakfast, and to persevere in so doing even when the result is occasionally or frequently unsuccessful. While straining to relieve the bowels, he may facilitate evacuation by pressing firmly the fingers in front and on each side of the coccyx, thus supporting the levator ani during contraction. Failing to obtain relief on the second day, a small cold water enema should be used to prevent further accumulation of feces in the rectum, and to restore tone and sensibility to the blunted nerves. The enema should never be larger than is required to dislodge the motion from the pouch of the rectum—nor should it be warm; at first it may be tepid, afterwards cold. When evacuation is obstructed by the lower part of the fecal mass becoming dry, relief may be obtained from emollient enemata and suppositories, such as infusion of linseed, decoction of marsh-mallow, solution of white of eggs, olive oil alone or in oatmeal gruel, or glycerine injected in small quantity into the rectum, and allowed

to remain there for some hours; or by the use of suppositories at bed-time, consisting of cocoa-butter, soap, or honey hardened by heat, either alone or combined with a stimulant to excite the flow of mucus into the rectum, or with extract of belladonna or of stramonium. Sedentary habits should be broken into. Exercise on foot or on horseback is specially to be commended, and carriage exercise to be avoided. While studying or reading the patient should walk about, and stand rather than sit at the desk. Gymnastics and out-of-door games are useful when a limited time only can be devoted to exercise. Excessive and exhausting exertion should be avoided. It is generally advisable to recommend early rising and cold bathing in the morning. In different cases one or other of the following may be found serviceable: a shower- or sponge-bath containing vinegar, bay-salt, or consisting of sea-water, or a cold sitz bath, douches directed to the abdomen; a cold water compress applied to the abdomen during the day or night or for three or four hours in the morning; friction or kneading in the course of the colon every morning and when at stool; an abdominal belt (flannel or elastic)—especially if the abdomen be pendulous. The interrupted current of electricity has been successfully employed as a special excitor of the muscular fibres of the intestines or of the abdominal wall.

Diet.—Vegetable should predominate over animal food. Greens (cabbage, lettuce, &c.) are useful, as well as fruits, which should be ripe, and taken on an empty stomach. Prunes or figs stewed in olive oil, or infusion of senna, prune-pulp, oils and fats, such as cod oil or olive oil, are also serviceable when they do not disturb the digestion. Bread made of bran (or three parts flour and one part coarse bran), of corn-meal, or of cracked wheat; oatmeal porridge, or wheat ground in a coffee-mill, boiled and salted and served like rice, only less thick, may assist in preventing constipation; if there be acidity and other symptoms of dyspepsia, however, these indigestible articles of diet should be avoided. Tobacco-smoking after meals in moderation sometimes relieves constipation. Cold water or carbonic acid water—a tumblerful at bed-time, or preferably on rising in the morning, may be useful. Much must be left to individual experience; sometimes coffee, or beer, or cider answers best. As a rule farinacea, astringent wines, and tea increase constipation.

2. Medicinal Treatment.—When dietetic and hygienic directions fail, they require to be assisted by medicinal agents. The ends to be secured are threefold:—1. To evacuate feces and gases which distending the large intestine, thwart peristaltic action. 2. To tone the walls of the bowel, and thus prevent accumulation of feces and the products of their decomposition. 3. To increase the flow of intestinal mucus. Remedies are usually variously combined for these purposes, and should be carefully adjusted to the requirements of each case, so as to meet the leading indications. Among the most useful aperients are aloes or its watery extract, rhubarb, colocynth, gamboge, and podophyllin, and either of these may be variously combined with extract of hyoscyamus or belladonna, extract of gentian,

extract of *nux vomica*, quinine, sulphate of iron, or *ipsecacantha*. The dose of the aperient should not exceed that required to secure gentle evacuation, and it varies with individuals. Purging exhausts torpid bowels, and perpetuates constipation. The bowels should not be pushed to more frequent relief than has been habitual with the patient from early life. The aperient, which should be varied in a prolonged course of treatment, should be very gradually dropped, while the intestinal tonics (*belladonna*, quinine, *nux vomica*, iron) are continued. The duration of treatment is prolonged until the aperient is almost entirely withdrawn. The remedies should be taken immediately or two or three hours after the principal meal. The treatment by *belladonna*, introduced by Bretonneau, was greatly prized by Trousseau (*see COLIC, Diseases of*).

In anæmic subjects a firm and prolonged course of iron should be aided by aloes, *nux vomica*, and arsenic. In hæmorrhoidal complications aloes should as a rule be avoided, and laxative electuaries should be prescribed; in some cases, however, it tones without irritating the rectum. Flatulent dyspepsia and tympanites are indications for the prescription of *nux vomica*, which, however, will not radically cure constipation. In obstinate cases the most useful remedies are colocynth — tincture (Prussian Phar.) 5 minims or more on sugar or in water three or four times a day, or 10 to 20 minims an hour before breakfast; extract or compound pill with small doses of croton oil, or with gamboge, elaterium, or other combinations; podophyllin with *belladonna* (Trousseau), *ipsecacantha*, and colocynth or aloes. A full dose of opium may liberate the bowels after the failure of the strongest purgatives, and constipation depending on inhibition of the sympathetic nerve from pain, will be relieved by opium with *belladonna*. Emetics, when frequently required, should be small in quantity, and at first tepid, then cold; for occasional use for the purpose of clearing away feces loading the large bowel, they should be large (from two to six pints) and warm (*see VOMES, Retention of*). The frequent use of large warm injections is injurious. Purgative waters, such as the Friedrichshall, Pullna, Hunyadi, or Carlsbad waters, given occasionally in small doses with warm water in the early morning, are often valuable adjuncts to a well-organized course of treatment. Constipation cannot, however, be cured by a course of saline purgatives, and may be greatly aggravated by it.

Numerous other drugs have been recommended in the treatment of habitual constipation, among which are nitric acid, arsenic with food in debilitated anæmic females, in the sedentary, or the old; tincture of benzoin—20 minims thrice daily, tincture of colchicum—a few drops after each meal; carbonate of iron; compound liquorice powder with sulphur—a teaspoonful at bedtime in water; tincture of veratrum viride—3 minims four or five times a day; or ox-gall dried, in pills.

GEORGE OLIVER.

A sound constitution may be defined as the harmonious development and maintenance of the tissues and organs of which the body is made up. It originates with the union of a healthy sperm and germ cell continues with the growth of the product under the most favourable conditions to adult life, and becomes gradually enfeebled with advancing age by the process of natural decay.

The constitution may be unsound in consequence of *deficient vitality*. This deficient vitality may be general, as is sometimes observed in the children of parents one or both of whom are in advanced life, or whose vitality on one side or the other has been reduced by excesses, such as alcoholic or venereal. Exhausted vitality from prolonged disease, *e.g.* phthisis or tertiary syphilis, affecting either parent, may determine the death of the offspring at an early period from mere failure of nutrition, or may cause it to succumb to acute disease not necessarily associated with any inherited tendency of a special kind. The deficient vitality may be restricted to certain tissues or organs, *viz.*, those concerned in the nervous, vascular, respiratory, or digestive systems. Thus amongst the most strikingly hereditary of diseases are those of degeneracy, such as emphysema, structural heart-diseases, atheroma of vessels, certain kidney-diseases, &c. Rightly interpreted, these diseases are of the nature of premature senility, attacking certain tissues or organs—as it may be seen to attack the hair or the cornea—from some inherent defect in their vitality.

The constitution may, in the second place, be unsound from some definite *inherited* form of disease. Although the constitution of an individual begins with his life, it is nevertheless the resultant of the constitutional peculiarities of many antecedents. This being so, tendencies to disease may date far back in the pedigree, to be called forth from time to time by favouring circumstances. We need, however, practically only go back a few generations in inquiring for those diseases which are well recognised as being hereditary. These form one section of the group of *constitutional diseases*.—Congenital syphilis, gout, scrophulosis, tuberculosis, cancer, asthma, and certain neuroses are all diseases which are apt to appear at certain periods of the life of the offspring, in consequence of some specific inherent defect of blood or tissue derived from his progenitors.

The constitution may, thirdly, become unsound at any period *subsequent to birth*. (a) This may be due to the surrounding conditions of life being evil. Deficient or impure air, insufficient or improper food, defective sunlight, over-work, intemperance, &c., may injure the constitution and give rise to diseases whose constitutional nature is sometimes strikingly shown in the tendency of some of them to become hereditary. Rickets, phthisis, and scrofula are examples. (b) The introduction of certain poisons into the system affects the constitution profoundly, and in some cases permanently, after the more obvious effects of the poisons have passed away. All the acute specific symptomatic diseases, including vaccinia, would come under this category. They render the organism, for a long period or for life, proof against subsequent

CONSTITUTION.—SYNON.: Diathesis, Habit, Conformation of body. Fr. *Constitution*; Ger. *Leibesbeschaffenheit*.

The constitution may be sound or unsound.

attacks of the same disease. Only in certain cases, however, can the soundness of the constitution be said to be impaired by such diseases, and then it is usually through the occurrence of sequelæ.

R. DOUGLAS POWELL.

CONSTITUTIONAL DISEASES. —

These may be regarded as diseases generated from within, in the course of the wear and tear, nutrition and waste of the body, in consequence of inherent or acquired weakness in its construction.

The applicability of the term 'constitutional' to disease is sufficiently explained in the preceding remarks on 'constitution'. The term may, however, be associated with a group of so-called 'general' diseases, in opposition to that which includes 'zymotic' or 'specific' diseases, which are generated by the introduction of some definite poison from without.

In our present state of knowledge, however, no very rigid lines can be drawn to separate local, general, constitutional, and specific diseases from one another. See *DISEASES*. CAUSES OF.

R. DOUGLAS POWELL.

CONSTRICTION (*constringo*, I bind together).—A narrowing, to a limited extent, of a canal or hollow organ, due either to a textural change in its walls, or to the pressure of a band surrounding it.

CONSUMPTION (*consumo*, I waste).—This is a term for any wasting disease, but it is generally applied to pulmonary phthisis. See *PHTHISIS*.

CONTAGION.—The word *contagion* is applied in pathology to the property and process by which, in certain sorts of disease, the affected body or part causes a disease like its own to arise in other bodies or other parts; and the Latin word *contagium* is conveniently used to denote in each such case the specific material shown or presumed, in which the infective power ultimately resides. See *ZYME* and *ZYMOISIS*.

The property of *CONTAGIOUSNESS* belongs to a very large number of the diseases which affect the human body. And in more than this direct way the property is of great interest to mankind. Contagiousness of disease is a fact not only for man, but apparently for all living nature; and the influence of contagion in spreading destructive diseases among domestic animals, and among those parts of the vegetable kingdom which contribute to the nourishment of man, is such as to make it of immense social importance that the laws of contagion should be well studied and understood. Further, just as contagion in the case of living bodies and their parts spreads disease from one to another, so, to an immense extent, in the case of certain matters which, though of organic origin, are not living, it spreads various processes of decay. The so-called 'fermentations' which yield alcohol and vinegar, as well as that in which putrefaction consists, are contagious affections of the respective matters in which they occur: every cheese-maker knows that moulds of different kinds spread by inoculation, each in its own kind, from cheese to cheese; and if the Greek proverb 'grape mellow to grape' is true of the

living fruit, the apple-loft gives analogous experiences of contagion among the fruit which is garnered.

The *RATIONALE* of the word 'contagion,' as now used, is that the property is understood to attach itself essentially to a material *contact*; not necessarily that, when infection is spread from individual to individual, the contact of the individuals must have been *immediate*; but that in all cases there must have been such passage of material from the one to the other, as was in itself at least a *mediate contact* between them. And similarly, in those very instructive illustrations of the process of contagion which are furnished within the limits of a single diseased body by the propagations of disease from part to part of it, we can in general easily see that infection advances from part to part, either in proportion as part touches part, or in proportion as the one receives from the other the outflow of lymph or blood or secretion.

The various *SPECIFIC MATTERS* which effect contagion in the living body, the respective 'contagia' of the given diseases, seem all to have in common this one characteristic: that in appropriate media (among which must evidently be counted any living bodily texture or fluid which they can infect) they show themselves capable of *self-multiplication*; and it is in virtue of this property that, although at the moment of their entering the body they in general do not attract notice, either as objects of sense or as causes of bodily change, they gradually get to be recognisable in both of these respects. Now, the faculty of self-multiplication is eminently one of the characters which we call *vital*, and when it is said that all contagia are self-multiplying things, this is at least very strongly to suggest that perhaps all contagia are things endowed with life.

In order to any general consideration of the question thus suggested, contagia may conveniently (even if but provisionally) be distinguished as of two main classes, differing, or at present seeming to differ, from each other in their mode of action on the organisms which they infect: one class, namely, that of *Parasites*; and the other class, that of the true or *Metabolic Contagia*. Of this separation, so far as present knowledge seems to justify it, the assumed grounds are: that each true Contagium, in proportion as it multiplies in the body, *transforms*, in a way which is specific to itself and is different from the ways of other contagia, the bodily material with which it has contact; while, on the contrary, the Parasite, however much it may grow or multiply in the body, produces no qualitative effects specific to itself, but only such effects as are of common kind to it and all other parasites—indications, namely, of its *mechanical intrusiveness* in the parts which it occupies, and sometimes of the *drain* which it makes on its host's general nutritive resources.

A.—Of *PARASITES*, in relation to processes of contagion, little needs be said in the present article. When an organism or part of it, in greater or less amount, inhabited by other organisms, animal or vegetable, which subsist on it, or its food or refuse, of course may be a centre of infection to other (if susceptible) bodies or parts, to which it can transmit live

parasites or their germs or seeds: for, when this transmission takes place, growth and self-multiplication, as in a colony, are the natural results which have to be expected; and in proportion as these occur, the newly-infected body or part gradually gets to suffer, like the old, from those particular derangements which make the type of parasitic disease. Some parasitic diseases, especially some of those of the skin, spread actively by direct contagion in ordinary intercourse; as for instance, scabies by the migration of its acari, and porrigo (among children) by the spores of its microphytes; and the spreading of such diseases where they exist may of course be to any extent facilitated by aggregation of persons and uncleanness of personal habits. There are cases in which parasitic disease spreads from animal to animal only in proportion as the one feeds on the other, and eats it with parasites still living in it; or in proportion as live parasite-eggs or larvæ, discharged from the body of one animal, get conveyed with food (especially on raw herbage and in water) into the bowels of another. Considerable epidemics of trichiniasis in the human subject have been traced, chiefly in Germany, to infection from the pig; in cases where pork, abounding with trichinæ, has been eaten, as sausage-meat or otherwise, in a raw or imperfectly-cooked state: and in Iceland the very great sufferings of the human subject and the cattle from echinococcus have been traced to the influence of the dogs in spreading contagion from the slaughter-house, where they eat hydatidised offal, to the kitchen-gardens and water-sources and pastures, where they discharge tape-worm eggs from their bowels. See PORRIGO, SCABIES, TRICHINA, HYDATID, &c.

The DISEASED STATES which consist in being colonised by parasites are diseases of indefinite duration, tending in some cases to indefinite increase. In cases where the disease consists in the presence of swarms of blood-sucking or otherwise exhausting animal parasites, symptoms of the blood-drawn will of course gradually arise; but otherwise the parasite, whether animal or vegetable, operates only as a mechanical presence. Skin and mucous membrane will be irritated in their superficial layers, and in some cases more deeply, by the animal or vegetable parasites which breed on or in them, just as they might be by dead mechanical irritants: solid organs having cystic entozoa in them will in like manner show evidence of irritation by encapulating the colonists; and the surrounding tissue will of course suffer compression and displacement in proportion as the colonisation (*g* in case of echinococcus) is compact and massive. In the case of trichiniasis—but, in our ordinary experience, in no other—the multiplication of the parasites, the burrowing of their young, and the general diffusion of these in the body, are processes of such extreme activity that, if the quantity of contagium taken into the stomach has been large, the innumerable local irritations suffice to make a very acute fever; but even in this extreme case, the more irritative type, though exaggerated, is essentially preserved.

As different sorts of animals are notoriously liable to different sorts of parasites, so, even among animals of one sort, as for instance in the

human kind, the LIABILITY of different bodies to receive particular parasite-infections, does not seem to be quite equal for all. Especially, the vegetable parasites seem to have their affinities determined or modified by the general state of health of the recipient; and there are cases in which it looks as if there ran in particular family-lines (perhaps with some slight chemical idiosyncrasy) a special liability to particular intestinal worms. There, however, is no reason to believe that in regard of the more important animal parasites, as particularly of trichina and the tæniæ, the susceptibility of individuals to attacks is other than universal and practically equal.

B.—The true or METABOLIC CONTAGIA (to which the rest of the present article will exclusively refer)—the contagia which, in their respective and specific ways, operate *transformingly* on the live bodily material which they affect, are perhaps the most important of all the incidental physical influences which concern mankind. Whether they may all, at some time hereafter, admit of being named, like the parasitic contagia, in terms of biological classification, is a question which needs not in the first instance be raised; for meanwhile the identity of each separate true contagium is settled in experimental and clinical observation by the uniformity of the operation of each on any given animal body which it affects. Each of the diseases propagates itself in its own form in as exact identity, as if it were a species in zoology or botany; and in each such repetition of the disease there is a multiplication—always a large, and sometimes an inconceivably immense multiplication, of material which has the same infective property. Evidences innumerable to that effect are under daily clinical observation in this climate in instances of smallpox, measles, scarlatina, whooping-cough, enteric fever, mumps, typhus, syphilis, cowpox, diphtheria, erysipelas, hospital gangrene, purulent ophthalmia and gonorrhœa, venereal soft-chancres and phagedæna, &c.: for, barring fallacies, no man ever sees any one of those diseases produced by the contagium of any other of them, and any man who has before him a case of any of them can see that, however minute may have been the quantity of contagium by which the disease was started, the patient's diseased body (part or whole) yields for the time an indefinitely large supply of the specific agent. It is more or less habitual to some of the diseases that the infectfulness of the patient is first made known to the observer by such *general pyrexia* as tells of change already far advanced in the circulating mass of blood; and it is only after this has shown itself, that other symptoms, adding themselves to the fever, complete the more or less complex type which establishes the identity of the disease. But in many of the diseases it may be the case (either naturally or as result of experimental infection) that the first, and in some diseases the main or even the only, effects of the contagion are *local changes*, passing where we can from the first observe them; and the broad facts of metabolic infection, as regular waste of bodily material with concurrent increase of contagium, are, in many such cases, among our most familiar experiences. Most instructive, too, are the facts of contagion which are to be learnt in the study

of tubercle: the contagium. introduced either by tubercular and certain septic inoculations through the skin, or internally by the infective action of the milk or diseased organs of tubercular animals if taken as food; and the contagium, when introduced, gradually spreading as it multiplies, and as lymph and blood carry it from the first infection-spot to other organs which now will repeat the process. And similarly in cancer (though the primary disease is at present of unknown origin and cannot be created by experiment) the repetition of the primary disease in secondary and tertiary propagations in the body of the sufferer is one of the most striking of all evidences of contagion; because of the great number of structural types which pass under the name of cancer, and the fidelity with which each of them is reproduced in the organ to which the contagion extends. A further fact of contagion, deserving notice in the present context, is the local spread of certain of these processes by continuity of tissue; as, for instance, in the continuous extension of phagedæna or hospital-gangrene from any centre of first inoculation, or of tubercular softening or cancer at the place where it begins: a mode of extension which indicates successive infective actions of matter on matter in spheres of ever-widening circumference; and the like of which, but in rudimentary degree, may be traced in the areola of any acute inflammation.

In the physiology of the metabolic contagia no facts are more characteristic or more important than those which show the RELATIVENESS of particular contagia to PARTICULAR RECEPTIVITIES of body. First, and in intimate connexion, as would seem, with a *chemical electiveness* of action which will presently be imputed to contagia, there is the preference which some particular contagia (however introduced into the system) show for particular organs of the body; so that, by the exercise of this preference, there is given to each of the diseases its own set of clinical and anatomical characters. Compare, as instances in this point of view, the respective local affinities of smallpox, enteric fever, mumps, syphilis, hydrophobia, &c.—Secondly, it may be noted that, in regard to some of the contagia, different persons, and particularly persons of different family-stocks, show original differences of susceptibility; original, namely, as distinguished from others, hereafter to be mentioned, which are acquired; so that, for instance, the severity with which scarlatina or diphtheria will strike in particular families contrasts with a comparative mildness of the same disease in other families, or perhaps even with cases of apparently complete personal immunity under exposure to the particular danger: and recent researches have seemed to suggest as possible that, in the very wide differences of degree with which tubercular disease prevails in different families, an essential condition may be, that the families have widely different degrees of original predisposition towards some of the septic contagia.—Thirdly, there is the extremely suggestive fact with regard to many of our best-known febrile contagia, that they run a

course of *definite duration*, and that in this course, provided the patient do not die, all present, perhaps all future, *susceptibility to the particular contagium is utterly exhausted from the patient*; so that re-introduction of the same contagium will no more renew that patient's disease than yeast will excite a new alcoholic fermentation in any previously well-fermented bread or wine. The inference from this fact seems unavoidable, that each such contagium operates with a chemical distinctiveness of elective affinity on some special ingredient, or ingredients of the body; and that exhausting this particular material in febrile process, which necessarily ends when the exhaustion is complete, is the bodily change which the contagium 'specifically' performs.—Of not all metabolic contagia, however, can it be said that their operation runs so definite and self-completing a course. For, first, there are particular *acute infections* which, as a rule, kill; either (as appears to be the case in splenic fever when affecting man) because of the extreme magnitude of the transforming process which the contagium sets up, or else (as appears to be the case in hydrophobia) because the elective incidence of the contagium is on an organ indispensable to life; so that in such cases there is in fact hardly such an event as passing alive through the whole process of the disease. And secondly, there are the *contagious dyscrasias* which are clearly characterised by their tendency to indefinite duration: syphilis, which oftener than not relapses in successive outbreaks, and often as years pass invades the body more and more deeply, and may after all never during life be ended; and tubercle and cancer, which, with almost invariable persistence, will in general steadily advance month by month to infect more and more of the body till the process eventuates in death.

The transmission of various contagious diseases in COMMUNITIES is of course greatly influenced, both in detail and in aggregate, by such differences of individual receptivity as were mentioned in the last section. Notably, as regards communities through which particular acute infections have had full run, fresh sparks of the contagium may find little or no fuel on which to act; and much new diffusion of the disease may not again be possible, till immigration, or births, or lapse of time operating in other ways, shall have reconstituted a susceptible population. And, given the susceptible population, circumstances of time and place are infinitely various (especially as regards quantity and quickness of personal or quasi-personal intercourse) in determining how far this population shall have particular contagia thrown in its way.

Also there are conditions, not primarily of a personal kind, which operate on a very large scale in determining the spread of some of the metabolic infections: giving to them respectively at certain times, in ways not hitherto understood, a *special increment of spreading-power*, and in some instances also *special malignity*; and thus enabling them respectively from time to time to come into comparative prominence in national life, and perhaps at once or successively in many different countries, in the form of so called *epidemics*. Thus, it is matter of familiar

* Compare Tennison's

'Little pitted speak in garnered fruit,

Which, rotting inward, slowly moulders all'

knowledge that the fevers which are most habitual to this country, scarlatina, measles, smallpox, enteric fever, are of nothing like uniform prevalence,—that scarlatina, for instance, will be three times as fatal in one year as in another, and that smallpox is liable to even greater exacerbations: and it is known that temporary differences of this kind are not exclusively local,—that, for instance (to quote a late official report) 'the epidemic of smallpox which began in England towards the close of 1870 and terminated in the second quarter of 1873 was part of a general epidemic outbreak of that disease, of world-wide diffusion, marked wherever it occurred by an intensity and malignity unequalled by any previous epidemic of the disease within living memory.' The wider the survey which we take of epidemiology, the more certain it becomes to us, that, outside the conditions which are independently personal or local, there are *cosmical conditions* which have to be considered. Doubtless there are great epidemiological facts—such, for instance, as the first spreading of smallpox to America, or in our own times the increasing frequency of Asiatic cholera in Europe, which may be ascribed to novel conditions of international intercourse: but there are others, equally great, to which apparently no such explanation can be applied. For what reason it is that cholera every few years has its definite fit of extension in India,—or why diphtheria, which scarcely had a place in history till it overran Europe in the 16th century, and which since then had been rarely spoken of, began again some twenty-odd years ago to be comparatively important in England,—or why the plague of the Levant has for the last two centuries been so unfamiliar to us,—or why the yellow fever of the Mississippi has in particular years raged furiously in parts of Europe,—or why our black-death of the 14th century, though apparently still surviving in India, has never but that once been in Europe,—or whither has gone our sweating-sickness of three centuries ago,—or whence have come the modern epidemics of cerebro-spinal meningitis: these, and many like questions, which cannot at present be answered, seem to be evidence enough that, in the making of epidemics, contagion and personal susceptibility may be factors in a partly *conditional* sense. Influences which are called 'atmospheric'—the various direct and indirect influences which attach to the normal succession and occasional abnormality of seasons, in respect of the insolation of our planet, and of the temperature and humidity of air and earth—are in general far too vaguely regarded as elements of interest in the present question, but are possible factors which no epidemiologist should omit from scientific consideration. For any definite knowledge which exists on the relation of particular conditions of season to the prevalence of particular epidemics, the reader is referred to the article *EPIDEMICS*, and to articles on the respective diseases.

In the *PASSAGE* of the metabolic contagia FROM PERSON TO PERSON various agencies may be instrumental,—bedding or clothing or towels which have been used by the sick, dirty hands, dirty instruments or other utensils, the washerwoman's basket, foul water-supply, stinking house-drains,

contaminated milk or other food, the common atmosphere, &c.; but differences of that sort are only differences as to the *means* by which *such communication is established with a diseased body* as brings its products into relation with healthy persons; and the disengagement of *infectious products* from the bodies of the sick is pathologically the one influential fact. As regards the products which ought to be deemed infectious, the specially-diseased surfaces and organs of the patient, and the discharges and exhalations which they respectively yield, must always be regarded with chief suspicion; but suspicion, however much it may insist on them, must never disregard other sources of danger. Of some of the metabolic contagia we practically know, and of many of the others we may by analogy feel sure, that, when a given body is possessed by one of them, no product of that body can be warranted as safe not to convey the infection. Presumption against every part and product of the diseased body is by everyone readily admitted where there are vehement general symptoms of disease: but it is important to know that not only in such febrile states, but even in states of chronic dyscrasy, and even at times when the dyscrasy may be giving no outward sign, the infected body may be variously infective. Thus, in regard to constitutional syphilis, it is certain that the mere utero-cutaneous discharge of the syphilitic woman, or the sperm of the syphilitic man, or the vaccine lymph of the syphilitic infant, may possibly contain the syphilitic contagium in full vigour, even at moments when the patient, who thus shows himself infective, has not on his own person any outward activity of syphilis. Similarly, in regard to tubercular disease, experiment has proved beyond question that the milk of animals suffering from tubercle will, if taken as food by other animals, infect them through the intestinal mucous membrane: and there are independent reasons for believing that the tubercular contagium (like the syphilitic) will at times during the dyscrasy be contained in the seminal fluid, and that men, tubercular perhaps only in some degree which is not immediately important to themselves, may by that secretion convey fatal infection to women with whom they have conjugal relations.¹ Regarding many of the metabolic contagia, conclusive evidence exists that, when they are in operation in pregnant women, the *fœtus* will in general be infected by them; and this though the diseases (*e.g.* smallpox, cholera, syphilis) be of the most different pathological types: but with regard to pregnant animals affected with splenic fever it is noticeable that Branell, in his extensive researches, found the blood of the *fœtus* not to be infective.

In general, each contagium has its own favourite WAY OR WAYS OF ENTERING THE BODY; and these preferences are not only of speculative interest, as attaching to varieties of nature and natural habits among the contagia, but are of obvious practical importance as measures of the widely different degrees in which the different contagia are qualified to spread in communities. Thus, *inoculation at broken surfaces of skin*

¹ See Dr. Weber, in *Chm. Soc. Trans.*, 1874.

or mucous membrane has long been known as the ordinary mode by which the infections of syphilis, hydrophobia, splenic fever, cowpox, and fæcy or glanders, get admission to the body; and our best knowledge of some other infectious diseases (notably of tubercle) has been derived from inoculations intentionally made with their contagia for purposes of study. While probably all infections which tend to be of general action on the body can be brought into action in that way, and while some infections are not known to pass by any other mode of transmission, there are many infections which spread freely from subject to subject by *atmospheric and dietetic communication*; and the meaning of these preferences is hitherto not fully known. It seems that some contagia are so acted upon by air and water, that they seldom or never reach the body in an effective state by those common means of communication,—some hardly, if at all, by water, and some not by air except with very close intercourse; and further, that, of contagia which reach the body in an effective state, some require, while others do not require, that an abnormal breach of surface shall give them special opportunity for taking hold. In some of the cases where a disease can be propagated in both ways,—i.e., certainly in smallpox, and apparently also in bovine pleuro-pneumonia, the artificially-inoculated disease tends to be much milder than the disease otherwise contracted, but pathologically it is difficult to conceive any essential difference between those different modes of contagion. It may be presumed that, in the modes which are not by true inoculation, acts which are comparable to inoculation take place on internal surfaces; that, for instance, when particles of scarlatina-contagium are caught in the tonsils, or inhaled into the bronchi, or swallowed into the stomach, they begin by penetrating the texture of the mucous membrane, and by thus effecting as real an inoculation, with regard to the blood, as that which art or accident provides in other cases through the punctured skin. That previous abnormal breach of surface by artificial puncture or otherwise is not necessary to allow the infection of mucous surfaces is illustrated in ophthalmia and gonorrhœa; where apparently no other condition has to be fulfilled than that a particle of the blenorrhagic contagium shall be deposited on the natural surface of the mucous membrane. It deserves notice that, while a considerable number of the worst diseases of the domestic animals admit of being communicated to man by artificial inoculation atmospheric communication seems to be very inapt, if not absolutely unable, to infect man with any one of them; and in this connection it may be of interest to remember that syphilis, one of the most familiar of human infections, but hitherto not traced to any brute ancestry, differs from our other current infections in requiring inoculation to transmit it.

When any metabolic contagium enters the animal body, it requires an INTERVAL OF TIME, and in most cases a considerable interval, before its morbid effects can become manifest even to skilled observation. The period of latency or so called *incubation* varies greatly in different cases. In hydrophobia it is very rarely less

than of one month, is certainly often of several months, and is said to be sometimes of years. In syphilis the inoculated spot remains generally for at least a fortnight, and may remain even as much as five weeks, without any ostensible change; and the roseola of the general infection will not be seen till some weeks later, when generally at least three months will have elapsed since the first inoculation. In the acute eruptive fevers, when their contagium is transmitted by air, the first changes which ensue on infection are not external, and we cannot be sure what early internal changes may take place; but in smallpox, the fever (which is the first overt sign) does not attract notice till about the twelfth day after infection, nor the eruption till two days later; and in measles the incubation-time, though perhaps less uniform, seems to be little (if any) shorter than that of smallpox. The septic contagia and the contagium of splenic fever seem to be of particularly quick operation; but even the most virulent septic contagium, when without admixtures which tend to complicate its action, will not begin sensibly to derange the infected animal till at least several hours after it has been inoculated. As regards the contagia last referred to, it is conceivable that the self-multiplication of the contagium in the form in which it proves fatal to life is a process which goes on continuously and uniformly from the moment of inoculation to the moment of death, and that the moment when signs of general derangement become manifest is the moment when this uniformly-advancing process has accumulated in the system a certain quantity of result:—but it does not seem easy to apply this explanation to the diseases of long incubatory period; and we can hardly conjecture what may be the latent processes—for instance of smallpox, during the first ten or more days after contagium has been received.

It is not yet possible to say, in any universal sense, with regard to the metabolic contagia, what is the ESSENTIAL CONSTITUTION of 'contagious matter,' or what the INTIMATE NATURE of the 'transforming power' which the particle of such matter exercises on the particles which it infects.—As regards the question of the FORCE, chemists, when they refer in general terms to the various acts which they designate *acts of fermentation*, allege that certain processes of change in certain sorts of organic matter induce characteristic changes in certain other sorts of organic matter, not by the common chemical way of double decomposition with reciprocally new combinations, but (so to speak) as a mere by-play or collateral vibration-effect of the chemical force which is in movement; and though language can hardly be more vague than this for any scientific purpose, it expresses clearly enough the conviction of experts that a certain great force in nature lies beyond their power even of definite nomenclature, much more of exact identification and measurement. In that most interesting, but most difficult and hitherto almost uninvestigated, branch of chemical dynamics, we are supposed to have our nearest clue to the scientific problems of the present subject-matter. It may be conceded that the 'contact-influences' which are duly recognised

as causing the fermentatory changes of dead organic matter have apparent analogues in many of the morbid influences of contagion: for the changes which chemists call 'fermentatory' are all catalytic or disintegrative of the organic compounds which they affect; and when living protoplasm is brought by contagion into processes of *characteristic decay*, the analogy seems sufficiently close to justify the word *symotic* in the naming of the nature of the process. But it must not be forgotten that, among immediate effects of contagion in the living body, are cases wherein the process (so far as we can yet see) is primarily not *catalytic* or *disintegrative*, but, on the contrary, *anaplastic* or *con-structive*. Thus, when tubercle gives rise to tubercle, whether by secondary and tertiary infection in a single diseased body, or by infection from the sick to the healthy, each new tubercle which the contagion brings into being is a *growth-product* of the texture which bears it. And similarly, when the innumerable varieties of cancerous tumour propagate themselves by contagion, each after its special type, in the bodies of the respective sufferers, it is growth, not disintegration, which we first see. It would seem that in those cases of anaplastic 'contact-influence' something far beyond the analogy of chemical fermentations must be involved, and, in view of some of them, the physiologist has to bethink himself of the analogy of that 'contact-influence' which becomes the mainspring of all normal growth and development, when the ovum receives spermatie impregnation.—As regards the ultimate *ORGANIC CONSTITUTION* of the several metabolic contagia—(each of them of course abstracted from accidental admixtures, and seen or conceived in the smallest and simplest units of quantity and quality in which its specific force can be embodied)—modern research seems more and more tending to show that the true unit of each metabolic contagium must either be, or must essentially include, a *specific living organism, able to multiply *vis* kind*. For with regard to those other contagia (as we may properly call them) which spread fermentatory processes in common external nature, and of which it is as clear as of the morbid contagia that they multiply themselves in proportion as they act, it seems to be established beyond reasonable doubt that the 'self-multiplication' of each of them as it acts is the infinite multiplication of a specific microphyte; and that this microphyte (acting apparently by means of a matter which it produces and from which it can be mechanically separated) is the essential originator of the fermentation.¹ This being the case in regard of those fermentations, it seems probable that the same is in substance true of the specific morbid changes which extrinsic contagia produce in the materials of

the living body: probable, namely, that low, self-multiplying organic forms, specific in each case for the particular disease which is in question, are essential to each morbid poison; that the increase of each contagium as it acts is the characteristic self-multiplication of a *living thing*; and that *this* (however obscure may yet remain its mode of operation) is the *essential originator of change* in the affected materials of the diseased body. The fact that low organic forms of the sorts now spoken of have often, or generally, been seen in the morbid products and tissues of persons with symotic disease, would not by itself be a proof, or nearly a proof, that the forms are causative of the morbid change: for obviously they might be mere attendants on the necrosis and decomposition of bodily material, availing themselves of the process (just as certain insects would) to feed and multiply: and in many of the cases in which micrococci have been seen in morbid material no direct proof could be given that the meaning of their presence was more than that. There are, however, some cases in which this proof has been completely established; and though such cases are at present but few, the significance of each of them in aid of the interpretation of other cases is of the highest importance. The researches of successive able observers in regard of the splenic fever of farm-stock, and those of Dr. Klein in regard of the 'pneumo-enteritis' (as he names it) of swine, have shown that in each of these cases the microphyte which attends the disease is botanically specific; that it and its progeny can be conducted through a series of artificial cultivations apart from the animal body; and that germs thus remotely descended from a first contagium will, if living animals be inoculated with them, breed in these animals the specific disease. It is equally well known that the organisms (spirilla) which are found multiplying in the blood during the accesses of relapsing fever are botanically specific; but in regard to this disease, experimental proof has not hitherto been given that the spirilla, if separately inoculated, will infect with relapsing fever. Studies as complete as those which have been made in splenic fever and pneumo-enteritis will no doubt sooner or later be made in regard to many other of the diseases, but their progress will necessarily be slow; partly because the objects which have to be scrutinised, and to which specific characters have to be assigned, are so extremely minute, and often so similar among themselves, that none but very skilled and very patient microscopical observers are competent to pronounce on them; and partly again because the conditions of the case are such as to limit very closely the field within which the essential experimental observations can be made. Meanwhile, however, the two diseases, regarding which the larger knowledge has been obtained, must be regarded as highly suggestive in regard of other diseases of the same pathological group, and particularly as giving importance to fragments of evidence (not by themselves conclusive) which have been gathered of late years in studies of some of these other diseases. Eminently this is true of the large family of the septic infections—including on the

¹ The doctrine to which the words in parenthesis refer (that the microphyte is not itself the ferment, but the producer and evolver of the ferment) tends to bring the case of these ferments into parallelism with that of the chylotropic and other functional ferments which more highly organised creatures produce for the purposes of their own economy. In the latter case the distinction between the ferment-yielding live bodies (say certain gastric cells) and their not-live product (say pepsin) is already familiar.

one hand erysipelas and pyæmia with its congeners, and having on the other hand tuberculosis intimately associated with it; and almost equally it is true of enteric fever and cholera and diphtheria, and of the smallpox of man and beast. Thus, though it would be at least premature to say of these diseases that they certainly have as their contagia *microphytes respectively specific* to them, it seems at present not too much to say that probably such will be found the case; and if as much may not yet be said of many other diseases which are due to metabolic contagia, it must be remembered that the right lines of study relating to contagia in this point of view have not till within very recent times been opened.

Of the NATURAL HISTORY of the contagia, considered independently of the part which they play in the living body, there are hitherto only the beginnings of knowledge. The absolutely first origin of contagia may perhaps not be more within reach of scientific research than the absolutely first origin of dog or cat; but their nearer antecedents—the states out of which they come when first about to act on the living body, and generally the variations which they and the common ferments exhibit under natural and artificial changes of circumstance, are within easy reach of investigation; and those humbler studies are likely to give very useful results. For some of our cases we seem to have an instructive analogy in the facts which Professor Moëser has put together in explanation of the blue-milk contagium of dairies: facts showing that the omnipresent penicillium glaucum, if its spores happen to alight in particular (morbid) sorts of milk, will operate distinctively on their casein as an anilin-making ferment, rendering the milk blue and poisonous, and imparting to each drop of it the power to infect with a like zymosis any normal milk to which it may be added.¹ In our own more special field, pathologists have already learnt that certain of the so-called 'morbid poisons'—the contagia of erysipelas, pyæmia and tuberculosis, are intimately related to the common ferment or ferments of *putrefaction*; and that the most vehement of these contagia can be developed by the artificial culture of successive transmissions in the living body from the comparatively mild contagium of any common inflammatory process.²

Two other directions suggest themselves as likely to lead to fields of useful observation and experiment. On the one hand, in *comparative pathology*, and with the tracing of contagion from animal to animal, there is the possibility that at least some lower and relatively worthless order of animals may be found the starting ground of fatal infections for higher orders; and this, perhaps, by contagia which in their former relations are of mere inflammatory significance. On the other hand, in *geographical pathology*, and with the tracing of contagion from place to place, local centres of contagium-

origination may possibly be found, in which the contagium, before it enters the animal body, will show itself an independent microphyte of the earth, first operating on the animal body as the essential force in a local malaria. Some of the worst pestilences known to the human race—yellow fever, cholera, perhaps plague, and also some of the diseases of cattle, have in their history facts which suggest this sort of interpretation: the supposition, namely, that certain microphytes are capable of thriving equally (though perhaps in different forms) either without or within the animal body; now fructifying in soil or water of appropriate quality, and now the self-multiplying contagium of a bodily disease. In regard to our own common ague, however, there seems every reason to suspect that its relation to soil is that of a microphyte; and though we know ague only as practically a non-contagious disease, we do not know that any little transfusion of blood from sick to healthy would not show it to be (in that way) communicable from person to person.

It needs hardly be said that exact scientific knowledge of the contagia, and of their respective modes of operation, is of supreme importance to the PREVENTION OF DISEASE. With even such knowledge of them as already exists, diseases which have in past times been most murderous of mankind and the domestic animals can, if the knowledge be duly applied, be kept comparatively, or absolutely, in subjection; and the fact that at the present time fully a fifth part of the annual mortality of the population of England is due to epidemics of contagious disease, is only because of the very imperfect application hitherto made of that knowledge. In the present article it is not necessary to state in detail the practice which ought to be adopted in the various different cases of infectious disease; but briefly it may be said that one principle is at the root of all such practice, whatever the disease to which it relates. This principle, which of course becomes more and more important in proportion as the infection is dangerous, and as the persons whom it would endanger are many, is the principle of *thoroughly effective separation* between the sick and the healthy; a separation, which, so far as the nature of the disease requires, must regard not only the personal presence of the sick, but equally all the various ways, direct and indirect, by which infective matters from that presence may pass into operation on others. Especially as regards the diseases which make serious epidemics, the principle of isolation is not carried into effect unless due care be taken to thoroughly disinfect in detail all infective discharges from the sick, and all clothing and bedding and towels and like things which such discharges may have imbued, and finally, as regards certain contagia, the rooms in which the cases have been treated; and in order to secure these objects, it is essential in all grave cases to make such nursing-arrangements and such arrangements of the sick-room (whether private or in hospital) that no retention or dissemination of infectious matters will escape notice. It is likewise essential that all who attend on the sick should be careful not to carry contagion to other persons; as they may but too easily do, particularly in scarlatina and

¹ Virch. Arch., vol. 42.

² See particularly Professor Sanderson's papers in successive yearly volumes of *Reports of the Medical Officer of the Privy Council* from 1865 to 1877. It concerns the second fact mentioned in the text to remember that apparently every 'common inflammatory process' includes more or less of textural changes which are necrotic and of toxic tendency. See Holmes's *System of Surgery*, first edition, article 'Inflammation.'

in certain traumatic and puerperal infections, if they omit to take special precautions against the danger. See articles QUARANTINE, DISINFECTANT, and PUBLIC HEALTH, and those on the special diseases.

The SOCIAL CONDITIONS through which, in our own country at the present time, the more fatal infectious diseases are enabled to acquire epidemic diffusion are chiefly such as the following:—that persons first sick in families and districts, instead of being isolated from the healthy, and treated with special regard to their powers of spreading infection, are often left to take their chance in all such respects; so that, especially in poor neighbourhoods, where houses are often in several holdings, and where always there is much intermingling of population, a first case, if not at once removed to a special establishment, will almost of necessity give occasion to many other cases to follow:—that persons with infectious disease, especially in cases of slight or incipient attack, and of incomplete recovery, mingle freely with others in work-places and amusement-places of common resort, and, if children, especially in day-schools; and that such persons travel freely with other persons from place to place in public conveyances,—that often, on occasions when boarding-schools have infectious disease getting the ascendant in them, the schools are broken up for the time, and scholars, incubating or perhaps beginning to show infection, are sent away to their respective, perhaps distant, homes;—that keepers of lodging-houses often receive lodgers into rooms and beds which have recently been occupied by persons with infectious disease and have not been disinfected;—that persons in various branches of business relating to dress (male and female) and to furniture, if they happen to have infectious disease, such as scarlatina or smallpox, on their premises, probably often spread infection to their customers by previous carelessness as to the articles which they send home to them; and that laundries further illustrate this sort of danger by carelessness in regard to infected things which they receive to wash;—that purveyors of certain sorts of food, if they happen to have infectious disease on their premises, by carelessness spread infection to their customers;—that streams and wells with sewage and other filth escaping into them are most dangerous means of infection, especially as regards enteric fever and cholera; and that great purveyors of public water-supplies, so far as they use insufficient precautions to ensure the freedom of their water from such risks of infectious pollution, represent in this respect an enormous public danger;—that ill-conditioned sewers and house-drains, and cesspools receiving infectious matters, greatly contribute to disseminate contagia, often into houses in the same system of drainage, and often by leakage into wells. Of the dangers here enumerated, there is perhaps none against which the law of England does not purport in some degree to provide. At present, however, they all are, to an immense extent, left in uncontrolled operation; partly because the law is inadequate, and partly because local administrators of the law often give little care to the matter; but chiefly because that strong

influence of national opinion which controls both law and administration cannot really be effective until the time when right knowledge of the subject shall be generally distributed among the people, and when the masses whom epidemics affect shall appreciate their own great interest in preventing them.

Whenever that time shall come, probably the public good will be seen to require, with regard to every serious infectious disease which is apt to become epidemic, that the PRINCIPLES which ought to be accepted in a really practical sense, and to be embodied in effective LAW, are somewhat as follows:—(1) that each case of such disease is a public danger, against which the public, as represented by its local sanitary authorities, is entitled to be warned by proper information; (2) that every man who in his own person, or in that of anyone under his charge, is the subject of such disease, or is in control of circumstances relating to it, is, in common duty towards his neighbours, bound to take every care which he can against the spreading of the infection; that so far as he would not of his own accord do this duty, his neighbours ought to have ample and ready means of compelling him; and that he should be responsible for giving to the local sanitary authority proper notification of his case, in order that the authority may, as far as needful, satisfy itself as to the sufficiency of his precautions; (3) that so far as he may from ignorance not understand the scope of his precautionary duties, or may from poverty or other circumstances be unable to fulfil them, the common interest is to give him liberally out of the common stock such guidance and such effectual help as may be wanting; (4) that so far as he is voluntarily in default of his duty, he should not only be punishable by penalty as for an act of nuisance, but should be liable to pay pecuniary damages for whatever harm he occasions to others; (5) that the various commercial undertakings which in certain contingencies may be specially instrumental in the spreading of infection—water-companies, dairies, laundries, boarding-schools, lodging-houses, inns, &c., should respectively be subject to special rule and visitation in regard of the special dangers which they may occasion; and that the persons in authority in them should be held to strict account for whatever injury may be caused through neglect of rule; (6) finally, that every local sanitary authority should always have at command, for the use of its district, such hospital-accommodation for the sick, such means for their conveyance, such mortuary, such disinfection-establishment, and generally such planned arrangements and skilled service, as may, in case of need, suffice for all probable requirements of the district.

Persons who are imperfectly acquainted with the scientific and social facts relating to the present subject-matter, or who have never seriously considered them, may think it would be over-sanguine to expect any general recognition of principles so peremptory as the above may at first appear to them; but, if so thinking, they would perhaps have under-estimated the rapidity with which knowledge is now increasing as to the common interests and mutual duties of mankind in respect of disease.

ous infectious disease. Fourteen years ago, when the so-called cattle-plague or steppe-murrain was imported afresh, as a long-forgotten disease, into this country, and was found to affect very large pecuniary interests, primarily of the chief land-owners of the United Kingdom, and secondarily of other classes, an immensely valuable stimulus was given to the education of the country, and especially of its Legislature, in regard to the preventability of the infectious diseases. And the remarkable zeal and ability which have been shown, in providing adequate laws and admirable administrative arrangements against the diffusion of steppe-murrain and other infectious diseases of Farm-Stock, are not likely to be found permanently absent in relation to the interests of Human Life, when once the true bearings of the subject shall have got to be popularly understood.

JOHN SIMON.

CONTINUED FEVERS.—CHARACTERS.

—Under the name of Continued Fevers is included a group of diseases which have the following characters in common:—

1. They are attended with *pyrexia*, or a febrile condition sustained for a more or less definite period of considerable duration, without intermission or very decided remission, and not due to any local inflammation. That is, the fever is *essential*, and not merely *symptomatic*. The distinguishing feature of *pyrexia* is unnatural elevation of the temperature of the body, but there are other symptoms scarcely less constant—increased frequency of the pulse, thirst, loss of appetite, furred tongue, headache, chilliness, and—if the temperature is high—various manifestations of disturbance of the nervous system.

2. They are clearly due to the introduction into the body of a *poison from without*, and this poison is *reproduced in the system*, so that continued fevers are communicable directly or indirectly from the sufferer to others. This statement would not apply to simple continued fever so called; but simple continued fever, when not a mild or abortive attack of one or other of the specific fevers, has scarcely anything in common with them.

3. The continued fevers rarely affect the same individual twice. An attack is *protective against subsequent attacks* of the same fever. This is much less manifest in relapsing than in typhus and enteric fever.

4. The continued fevers have a more or less *definite duration*. A certain time intervenes between the exposure to the poison and the onset of the disease, which is called the period of incubation; and the disease is divisible into the stages of invasion, dominance, and decline.

5. In two out of the three continued fevers there is a characteristic *cutaneous eruption*.

ENUMERATION.—The continued fevers are typhus, enteric, and relapsing fever. Common continued fever, or febricula, often associated with them for the sake of convenience, resembles them only as consisting in *pyrexia* not traceable to any known local inflammation. It does not conform to the characteristics enumerated, and cannot be brought within any definition which applies to the true fevers.

DIAGNOSIS.—The continued fevers have to be

distinguished from the intermittent and remittent fevers on the one hand, and from the eruptive fevers and some other diseases on the other.

1. From *intermittent* and *remittent* fevers they are distinguished clinically by the comparatively sustained high temperature; but were this all the continuous character sometimes assumed by intermittents and the remittent type occasionally seen in enteric fever—especially in children—would bring them close together. The essential distinction is that indicated under the second head, and is mainly ætiological. Both kinds of fever are due to a poison received from without; but while in continued fevers the source of the poison is for the most part a previous case of fever of the same kind, and the poison is generated anew in the subject of the disease, remittents and intermittents are of malarious origin, and the poison is never reproduced in the system, and therefore never communicated by the sufferer.

The formation of the specific contagium of continued fevers within the system during the disease is of course the cause of their spread by contagion. The mode of this spread is different for the different fevers. Typhus and relapsing fever are directly contagious in an eminent degree; the poison is contained in the emanations from the skin or lungs, and is capable of entering the blood of healthy persons by being breathed or swallowed; it may also be carried by fomites. Enteric fever, if directly contagious at all, is very slightly so; the contagium is apparently not given off in the breath or perspiration, but chiefly or exclusively from the bowels, and the disease is spread mainly by the contamination of drinking water, or, more rarely, by sewer gases or by the emanations from typhoid excreta, especially after long residence in sewers.

2. The distinctions between the continued and the *eruptive fevers* remain to be pointed out. They are of a very slight character. All the characters given of the continued fevers, including the occurrence of a cutaneous eruption, are common to them and the eruptive fevers. The differences are as follows:—

- a. The liability to the eruptive fevers is almost universal in the absence of protection by a previous attack, and is little affected by the state of health of the individual, while the liability to continued fever is very variable in different persons, and even races, and is greatly influenced by external conditions. There is no parallel in the eruptive fevers to the predisposition to typhus and relapsing fever generated by overcrowding and famine.

- b. The protective influence of a previous attack is more marked in the eruptive fevers, though not to such a degree as would constitute an important distinction. Instances of small-pox after a previous attack, or after vaccination, and second attacks of measles and scarlet fever, are not very uncommon.

- c. While in the eruptive fevers the specific poison is considered to be invariably derived from a previous case, this cannot be said with the same confidence with regard to the continued fevers. It is true that in by far the largest proportion of attacks of typhus, enteric, and relapsing fevers the source of the poison can be

traced, and that as the experience and trained skill brought to bear on the search increase, the fewer are the examples in which it fails; but it cannot yet be said definitely that these fevers are not generated anew under certain conditions. The constancy with which typhus and relapsing fever follow in the track of overcrowding and starvation is suggestive of spontaneous origin; but in this country typhus is never so completely extinct that foci of infection are wanting, and epidemics of relapsing fever may be imported. Enteric fever, again, appears from time to time under circumstances which appear to exclude the possibility of the poison having been derived from a previous case, though in most instances of epidemic prevalence of the disease, there is conclusive evidence of specific and not merely general contamination of the air or water. It is not, however, necessary to enter upon this controversy here, or to do more than allude to the question whether or not their contagia are of the nature of organic germs. See *CONTAGION*; and *ZYMA*.

The fevers will be fully described under their respective names. WILLIAM H. BROADBENT.

CONTRACTION, Muscular (*contraho*, I draw together).—A term applied to the action or to the shortening of a muscle from any cause, whether in health or in disease. See *SPASM*.

CONTRA-INDICATION.—Any circumstance which forbids the employment of therapeutic measures otherwise indicated.

CONTRE-COUP (Fr.), Counter-stroke.—An injury of a part opposite to and distant from that to which force is applied, as by a fall or direct blow. Contre-coup is chiefly observed in injuries of the skull.

CONTUSION (*contundo*, I bruise)—A bruise or injury of the soft parts without laceration of surface.

CONVALESCENCE (*con* and *valesco*, I grow well).—The period of convalescence signifies that period during which a patient is progressing towards recovery, and is returning to a state of health after having suffered from an illness. When the health has been completely restored, convalescence is said to be established, and the patient is regarded as convalescent. The word is used most commonly in association with fevers, inflammatory diseases, and other acute affections. Convalescence may be ushered in by a crisis, and become speedily established; or it may be very slow and protracted in its progress, which is also often interrupted by relapses, complications, or sequelae. Patients frequently require careful watching and judicious treatment while becoming convalescent, as they are apt to retard or even prevent their recovery, and to lay the foundation for permanent disease by neglect of due precautions, especially as regards their diet. Much injury is not uncommonly inflicted by the injudicious administration of medicines, and the employment of other means which are supposed to hasten convalescence.

FREDERICK T. ROBERTS.

CONVOLUTIONS OF THE BRAIN
and **CORTEX CEREBRI**, Lesions of.—

The pathology of the cortex cerebri is a subject which, notwithstanding the extensive literature relating to cerebral disease, is still comparatively in its infancy. The older records and observations made while the idea was still prevalent, that the convolutions of the brain had no definite dispositions and relations, and that the various parts of the hemispheres were functionally equivalent, are not sufficiently exact to be made the basis of trustworthy clinical and physiological conclusions. Recent anatomical investigation into the topography and homologies of the cerebral convolutions, and the experimental researches of Hitzig, the writer, and others in reference to the results of electrical irritation of the brain, have directed greater attention to accurate topographical descriptions of the lesions of the cortex in connexion with observed clinical symptoms. As yet, however, the reliable pathological material is not very extensive, though it is every day accumulating, more particularly by the labours of Charcot and his followers in France, and Hughlings Jackson and others in this country. Up to a comparatively recent date physicians and physiologists generally held by the views of Flourens, based on experimental investigation of the brains of the lower classes of animals. According to Flourens the hemispheres were concerned purely with intelligence—a faculty one and indivisible; and each part of the hemisphere possessed the functions of the whole, so that, if part were destroyed, functional compensation might be effected by the parts which remained. These views seemed satisfactorily to explain the cases, not uncommon, in which, notwithstanding the existence of extensive lesions in the hemispheres, no symptoms were observed during life. The frequent association of aphasia with a limited lesion of the cortex cerebri, vaguely indicated by Bonillaud and Dux, and definitely fixed by Broca at the posterior extremity of the third left frontal convolution, was a step towards localisation of function in the brain, which, however, met with much opposition and counter-facts. The clinical and pathological observations of Hughlings Jackson in reference to the causation of limited and unilateral epileptiform convulsions were an important contribution to the physiology and pathology of the cortex. These convulsions he attributed to irritative or discharging lesions of the grey matter in the neighbourhood of the corpus striatum in the opposite hemisphere.

Physiological experiment has demonstrated the correctness of the views advanced by Hughlings Jackson, and shown that, not only can movements be excited by electrical irritation of certain regions of the cortex, but also that definite combinations of muscular movements uniformly result from stimulation of certain specialised areas within this region. The interpretation of these facts, now no longer disputed, has been much debated, but the views the writer has elsewhere expressed at length (*Functions of the Brain*) seem in accordance with the most recent and careful pathological and clinical research, viz. that the brain is divided into a motor and a sensory region, and that in each there are definite centres with definite functions, and that the symptoms of cortical lesions depend

on the locality of the lesion, and on whether it is unilateral or bilateral.

Physiological experiment is, as to precision in its results, considerably in advance of clinical observation, and, from the nature of the two methods, this is what might be expected.

The investigation of diseases of the brain is surrounded by special difficulties. Though, as shown by physiological experiment, the brain is capable of being mapped out into different regions possessing different functions, yet the brain acts as a whole, and it is not always easy to analyse the facts of disease, and to distinguish with certainty between the effects directly dependent on the locality of the brain and those due to the indirect influence exerted on the functions of neighbouring regions and on the brain as a whole. And when, moreover, we take into account the vague manner in which it has been the custom to define the locality of the lesion, it is not surprising that so little has as yet been accomplished in reference to the localisation of cerebral disease.

But, besides these difficulties there are others, of greater magnitude and less easy to overcome, inherent in the subject itself. For the brain, besides being concerned with certain functions which we can investigate objectively, viz. sensation and voluntary motion, is the organ of mental operations, and as the same parts have an objective and subjective function, it is obvious that cerebral diseases may manifest themselves mentally as well as bodily. These two sides of brain-function and their disordered manifestations have been in a great measure artificially separated for convenience in treatment, and the relation between the physiological and the psychological has not been duly recognised. And yet it is obvious that until psychological phenomena have been reduced in ultimate analysis to their anatomical and physiological substrata we can have no rational medical psychology, as distinguished from empiricism or mere speculation, available as a guide to the diagnosis and treatment of cerebral disease in its subjective or mental manifestations.

That the brain is diseased in insanity, functionally or organically, is a fact now universally admitted; but it is also true that the lesions which cause objective symptoms in the domain of motion and sensation need not cause mental derangement, and also that lesions which cause mental derangement need not manifest themselves in any discoverable disorders of sensation or motion. In fact, for purposes of ideation we have practically two brains; for, though motion and sensation will be paralysed on the opposite side by destruction of one hemisphere, yet intelligence and thought are possible through the hemisphere which remains.

Various forms of lesion have been found in the brains of the insane, such as morbid conditions as to vascularity, degeneration of the blood-vessels, degeneration of the nerve-cells, neuroglia, membranes, &c.; but no constant relation has as yet been established between any one form of degeneration and any one form of mental alienation, or between the latter and any localised lesion. Nor has it been clearly established whether the forms of degeneration found

in the brains of the chronically insane are the result or the cause of the mental disorders. An exception, however, is to be made in favour of general paralysis of the insane, where there seems to be a definite connexion between the anatomical lesion and the symptoms manifested. In this disease we find as a constant, if not the only factor, a form of chronic encephalitis, affecting chiefly the cortical regions which physiological experiment has shown to be the motor zone of the hemispheres. This lesion is associated with progressive motor paralysis, varied with intercurrent epileptiform and apoplectiform seizures, and with mental symptoms characterised generally by exalted ideas and delusion as to wealth, power, and grandeur. The motor symptoms are readily accounted for by the locality and character of the cerebral lesion, but the relation between this and the mental symptoms is a subject which psychological analysis has yet to elucidate.

Another link between the physiological and psychological aspects of brain-function is furnished by aphasia, in which, with a definite anatomical lesion, there is a definite psychological defect (*see* APHASIA). But beyond these the relation between morbid mental manifestations and morbid conditions of the brain, and their joint relation to the bodily symptoms, remain involved in great obscurity.

The objective symptoms of cortical lesions depend on their locality, and on whether they exercise an irritative or destructive influence on the parts they invade. From the localisation point of view alone the intimate nature of the morbid process is unimportant, except in so far as its irritative or destructive character is concerned. Lesions, such as tumours, which from their very nature exercise important indirect effects on the encephalon as a whole, apart from their effects on the regions which they directly invade, can rarely be exactly localised, owing to the difficulty of separating the direct and indirect symptoms from each other and referring each to its exact cause. Also no rigid conclusions as regards localisation can be drawn from morbid affections of the hemispheres which extend over a large area, such as the various forms of meningitis and meningo-encephalitis. In all these cases the nature of the affection must be diagnosed from its own general and special characters; its position and extent in the brain being arrived at approximately from a consideration of the effects of accurately circumscribed lesions, as determined by careful clinical and pathological observation and physiological experiment.

The brain may be considered as divided into a *motor* and a *sensory* zone.

Motor Zone.—The motor zone includes the convolutions bounding the fissure of Rolando, viz. the ascending frontal and the bases of the three frontal convolutions, the ascending parietal and postero-parietal lobule, and the internal surface of the same convolutions or paracentral lobule. In this zone are differentiated centres for the movements of the limbs, head, and eyes, the muscles of expression, and those of the mouth and tongue. The centres of the leg and foot are situated in the postero-

parietal lobule, those for the arm in the upper third of the ascending frontal, those for the hand and wrist in the ascending parietal, those of the facial muscles in the middle third of the ascending frontal and base of the second frontal those for the mouth and tongue at the lower third of the ascending frontal at the base of the third frontal, and for the platysma at the lower extremity of the ascending parietal, just posterior to the mouth-centre. The posterior third of the upper frontal convolution and corresponding part of the second frontal, contain the centre for the lateral movement of the head and eyes.

The frontal regions in advance of this centre, though anatomically related to the motor division of the internal capsule, do not seem directly connected with motor manifestations as judged by the negative effects either of irritation or extirpation.

Irritative lesions of the motor zone proper, such as may be induced by syphilitic lesions, tumours, spicula of bone, depressed fractures, thickening of the membranes, &c., cause convulsions, which may remain limited to one limb or one group of muscles without loss of consciousness, or affect the whole of the opposite side with loss of consciousness, or become more or less bilateral with all the symptoms usually observed in so-called idiopathic epilepsy.

If the convulsive phenomena begin always in the same way, and if they frequently remain localised in one limb or one group of muscles, and especially if paralytic symptoms manifest themselves, the exact position of the lesion in the opposite hemisphere may be accurately diagnosed. (See cases by Hughlings Jackson, *Clinical and Physiological Researches on the Nervous System* (reprints), 1873; Dr. Dreschfeld, *Lancet*, Feb. 24, 1877; Dr. Bramwell, *Brit. Med. Journ.*, Aug. 28, 1875; MM. Charcot and Pitres, *Revue Mensuelle*, 1877.)

Destructive lesions of the motor zone cause general or limited paralysis of voluntary motion in the opposite side of the body, according as the lesion affects the whole of the motor zone or is limited to special centres within this area. The causes of destructive lesions of the cortex may be various—hemorrhage, laceration by wounds, &c. One of the most common causes is embolism or thrombosis of the arteries supplying the cortical motor area. These are derived from the Sylvian artery of the middle cerebral. The cortical branches may be occluded without interfering with the circulation in the corpus striatum, which is supplied by special branches, as shown by the researches of Duret and Heubner.

When the motor zone is affected by general destructive lesion, complete hemiplegia of the opposite side results, in all respects like that resulting from destructive lesion of the corpus striatum and anterior portion of the internal capsule. In this form of paralysis the loss of motion is most marked in those movements which are most independent, hence the arm is more paralysed than the leg or face, and the hand more paralysed than the shoulder movements of the arm. This has been accounted for by the fact, that the centres for bilateral movements are intimately associated in the lower

ganglia; hence the stimulus from one hemisphere can to a certain extent call forth the action of

FIG. 12.—Side view of the Left Hemisphere of the Monkey. The areas have the same signification as in the next figure.

FIG. 13.—Side view of the Left Hemisphere in Man, with the areas of the cerebral convolutions. The effects of stimulation of each area, as ascertained by experiments on the brain of the monkey, are subjoined.

1. Postero-parietal lobule. Advance of the opposite hind limb, as in walking.
- 2, 3, and 4. Around the upper extremity of the fissure of Rolando. Complex movements of the opposite leg and arm, and of the trunk, as in swimming.
- a, b, c, d. Ascending parietal convolution. Individual and combined movements of the fingers and wrist of the opposite hand. Prehensile movements.
5. Posterior extremity of the superior frontal convolution. Extension forward of the opposite arm and hand.
6. Upper part of ascending frontal convolution. Supination and flexion of the opposite forearm.
7. Median portion of ascending frontal convolution. Retraction and elevation of the opposite angle of the mouth.
8. Lower part of the ascending frontal convolution. Elevation of *ala nasi* and upper lip, with depression of lower lip.
- 9 and 10. Inferior extremity of ascending frontal convolution (Broca's convolution). Opening of the mouth with (9) protrusion and (10) retraction of the tongue—region of aphasia. Action bilateral.
11. Between the inferior extremities of the ascending frontal and the ascending parietal convolutions. Retraction of the opposite angle of the mouth; and the head turned slightly to one side.
12. Posterior portions of superior and middle frontal convolutions. Eyes opened widely; pupils dilated; head and eyes turned towards opposite side.
- 13 and 14. Supra-marginal lobule, and angular gyrus. Eyes moved towards the opposite side, with an upward (13) or a downward (14) deviation. The pupils generally contracted. (Centre of vision.)
15. Infra-marginal (superior temporo-sphenoidal) convolution. Pricking of opposite ear; head and eyes turned to opposite side; pupils largely dilated. (Centre of hearing.)

the conjoint motor nuclei. The electrical contractility and nutrition of the muscles is not effected by paralysis of cerebral origin. The nutrition of the muscles may, however, suffer from disuse, and frequently paralysis of cortical origin are followed after a time by rigidity and contraction, accompanied with descending secondary sclerosis of the motor tracts of the crura, pons, and lateral tracts of the spinal cord. In some cases the descending degeneration invades the anterior cornua of the spinal cord, and atrophy of the paralysed muscles ensues. Occasionally from limited lesions of the cortical motor area complete hemiplegia may occur on the opposite side for the time at least. This is to be explained by the fact that sudden establishment of a destructive lesion may cause such commotion or perturbation of the centres in general, that their functions are for the time suspended. But in such cases those centres which have been only functionally suspended will again resume their functions, and the paralysis will disappear except of those movements the centres of which have become permanently damaged. Limited lesions of the motor zone cause paralysis of those movements the centres of which the lesion invades. The result is not complete hemiplegia, but a *monoplegia* or *dissociated paralysis*. Hence, from a cortical lesion we may get a paralysis of the arm, or of the arm and face, or of the leg and arm, or of the face alone, or of the lateral movements of the head and eyes. Numerous examples of these monoplegias resulting from limited cortical lesions have been collected by Charcot and Pitres (*Revue Mensuelle*, Jan. 1877. *et seq.*; abstract in *Lond. Med. Record*, April, 1877). The morbid process which, while circumscribed at first, causes a monoplegia, may advance to other centres, and after a time produce general hemiplegia of the opposite side. Hemiplegia so resulting is a succession of monoplegias, and is a sure indication of cortical disease. It is to be noted that destructive lesion of the mouth-centre (Broca's region) on one side does not cause paralysis of articulation, owing to the fact that each centre has a more or less complete bilateral influence over the movements of the mouth and tongue. Destructive lesion of this centre in the left hemisphere generally gives rise to aphasia without paralysis of articulation (*see* APHASIA). In bilateral lesions there is both aphasia and paralysis of articulation (*see* Dr. Barlow's case, *Brit. Med. Jour.* 1877, vol. ii. p. 103). Limited cortical motor lesions are frequently associated with transitory rigidity of the opposite side of the body; and if the lesion is complete, the local paralysis or monoplegia will remain permanently, and may be accompanied by late rigidity and descending sclerosis of the motor tracts, as has been shown by Charcot (*op. cit.*). These monoplegias frequently alternate with unilateral convulsions, owing to the morbid process occasionally inducing irritation of the neighbouring centres.

Destructive lesions of the frontal and orbital regions cause no motor paralysis or any very evident physiological symptoms. In the recorded cases of bilateral lesions symptoms of dementia to a greater or less extent have been noted.

Sensory Zone.—From experiments on the brain of monkeys by means of the complementary methods of excitation by the electric current, and destruction of the grey matter of the cortex, the writer has arrived at the conclusion that in the regions lying posterior to the motor zone there are differentiated centres of sight, hearing, touch, smell, and taste. The sight-centre is situated in the angular gyrus, and embraces also the occipital lobe—the occipito-angular region; the centre of hearing is localised in the superior temporo-sphenoidal convolution; the tactile centre is situated in the hippocampal region; while the centres of smell and taste are situated together at the lower parts of the temporo-sphenoidal lobe.

Destructive Lesions.—Unilateral destruction of these sensory centres does not, however, appear to permanently abolish sensation on the opposite side of the body. It is only when the lesion is bilateral and in corresponding points that the loss of sensation is thorough and permanent. Hence the fact is to be accounted for, that in man, as a rule, unilateral destructive lesions of the regions indicated are latent, or not, so far as at present known, accompanied by any objective symptoms. Numerous cases of this kind are on record. No secondary descending degeneration of the spinal cord has been observed in these cases.

Until evidence is increased from human pathology of the occurrence of loss of sensation from lesion of the cortex—and this the writer holds is to be looked for in bilateral destructive lesions—pathologists in general reserve their opinion as to the explanation of the latency of the lesions in question.

But though the pathological evidence in favour of the localisation of distinct sensory centres is as yet comparatively slender, it is daily increasing. Though numerous cases are on record of lesions in the angular gyri and occipital lobes without symptoms as regards vision, there are others, more particularly of lesions of the medullary fibres of this region, in which hemiopia towards the side opposite the lesion has been observed. Some of these cases may perhaps be explained by direct or indirect lesion of the optic tract, but others cannot be so accounted for. For other facts bearing on this question the reader is referred to a paper by the writer on Cerebral Amblyopia and Hemiopia, *Brain*, xii. 1881.

It has been established by the researches of Turck, Charcot, &c., that destructive lesions of the posterior third of the internal capsule, external to the optic thalamus, cause hemianæsthesia of the opposite side of the body. The hemianæsthesia of organic origin exhibits the same symptoms as are observed in what is termed hysterical hemianæsthesia. In this condition there is loss of tactile sensation and more or less complete loss of sight, hearing, smell, and taste, on the side opposite the lesion. The affection of sight, which is not accompanied by any changes in the eye discoverable by the ophthalmoscope, is characterised by dyschromatopsy, and a remarkable contraction of the field of vision. The loss of hearing is very marked, if not absolute, and similarly as regards smell

and taste. It is evident that the lesion situated in the medullary fibres is not an affection of sensory centres, and that it is simply a solution of continuity of the centripetal paths which radiate out into the differentiated sensory centres of the cortex. The exact destination of the special sensory paths the writer has indicated above, and to this the special attention of physicians and pathologists should be directed. The writer is likewise of opinion that the loss of smell and taste, which is occasionally observed to result from a blow on the occiput or vertex is in many cases due to injury by counterstroke to the centres of smell and taste, which are situated in such a position as to be specially affected by violence so directed. There is no doubt that in some cases the loss of taste might be accounted for by rupture of the olfactory tract or nerves, such as those in which taste is lost only for flavours, which are compounds of smell and taste. But there are others in which there has been clear loss both of smell and taste independently of each other; cases which can only be satisfactorily accounted for, in the writer's opinion, in the manner which he has indicated.

Irritative Lesions.—Though the pathological evidence in reference to the localisation of sensory centres is as yet but deficient, at least as regards paralysis of the special senses from destructive lesions of the cortex, there is good reason for believing that in cases of insanity, accompanied by sensory hallucinations, as also in certain cases of epilepsy ushered in by subjective sensations, such as flashes of light and colour, loud sounds, disagreeable tastes and smells, &c., the phenomena are the result of some morbid irritation of the cortical sensory centres, the anatomical substrata of ideation.

D. FERNIE.

CONVULSIONS.—**DEFINITION.**—This term is commonly given to more or less general, purposeless muscular contractions, occurring simultaneously and successively for a variable time. It is also, however, applied at times to certain more localized purposeless contractions, though these would be more appropriately (and are in the majority of cases) termed **SPASMS**. The latter, like Convulsions, are of two kinds, *tonic* and *clonic*.

CLASSIFICATIONS.—Convulsions have been variously classified by different authors according to the different points of view from which they have been regarded. Looking to their causation, there is both a clinical and a physiological division into classes. From the former standpoint we have (1) primary or essential convulsions; (2) sympathetic convulsions; and (3) symptomatic convulsions; whilst from the physiological point of view they have been divided into (1) centric and (2) excentric. These classifications are arbitrary and will not stand the test of a critical examination, though the first of them is to a certain extent useful. Again, looking to the distribution of the convulsions, or to the parts involved, their classification by different writers may be summarized as follows:—(1) *External*—*a*, general; *b*, unilateral; *c*, partial; (2) *Internal*.

These various terms need little explanation, though something requires to be said in regard to them.

Convulsions are termed *primary* or *essential* when they occur either without assignable cause, from mental or moral perturbations, or as a result of some local irritation. They are called *sympathetic* when the convulsions declare themselves as a prelude to, or in the course of, any of the specific fevers, as a consequence of acute pulmonary or renal affections, or in association with disordered states or structural diseases of any of the organs of the body other than those of the nervous system, whilst the name *syndromatic* has been applied to the convulsions which occur as a result of injury or structural disease of the nervous system itself. The unilateral convulsions which affect one half of the body only, as well as other more partial convulsions, are almost entirely confined to this latter group, though general convulsions of the syndromatic type are perhaps just as frequently met with. The so-called *internal convulsions* constitute an ill-defined group, the members of which are scarcely worthy of the name of convulsions at all. They are rather tonic or clonic spasms of particular parts. The best known member of this group is laryngismus stridulus (see separate article thereon), though we may also include another much less grave, though often obstinate malady, viz. a spasmodic and frequently recurring hiccup. Some would include angina pectoris also in this group.

Convulsions, either tonic or clonic, or both, enter into or form the semeiological basis of five principal diseases having separate places in our nosology. These are *Eclampsia*, *Epilepsy*, *Tetanus*, *Hydrophobia*, and *Chorea*. All but the first of these diseases will be fully considered in their respective places, so that *Eclampsia* alone would remain. But *Eclampsia* and *Convulsions* are convertible terms, meaning almost absolutely the same thing. The former term, indeed, is useless except for the mere purpose of literary precision. In epilepsy and in eclampsia we have equally to do with convulsions, which are now admitted by almost all modern writers to be quite indistinguishable from one another. The former name, however, is given to convulsions which have a known tendency to recur at variable intervals; whilst the latter has been commonly applied to convulsions which are either solitary or, if not exactly so, which occur as a closely successive cluster or group, more or less distinctly sympathetic with some general or local bodily condition. Seeing that there is, in a very large number of cases, almost nothing in the nature of the attack itself to enable a medical man, called to a patient in convulsions for the first time, to say whether he has to do with an attack which will be repeated or not, it is easy to understand that eclampsia is a word more frequently to be seen in books than to be heard at the bedside. In books we may read of eclampsia neonatorum, the eclampsia of parturient women, and uræmic eclampsia; though the more common clinical equivalents are infantile convulsions, puerperal convulsions, and uræmic convulsions. The distinction between epilepsy and eclampsia is, therefore, one which is to a very great extent purely artificial.

Convulsions have a frequent though less constant relationship also with many other affec-

tion, such as general paralysis of the insane, tubercular meningitis, chronic hydrocephalus, hemiplegia, and hysteria.

Ætiology.—The causes of convulsions are oftentimes more than usually complex, constituting a web of causal conditions partly made up of (a) predisposing, partly (b) of exciting, and partly (c) of proximate elements. It is often the fashion to pick out some one of the most prominent or easily recognizable of these factors, and speak of it as 'the cause' of the attack. It must never be forgotten, however, that this so-called cause, in any given case, may be able to act as such only when in conjunction with certain other more obscure, though perhaps not less potent, co-operating conditions. Without the conjoint influence of the latter it might have been quite powerless to produce any such results. Hence the proverbial uncertainty in regard to the action of any of the more important factors, or so-called 'causes,' upon different individuals whose age, state of health, predisposition, or surrounding conditions are not similar.

The question of the causation of convulsions resolves itself, however, into two distinct departments, one of which is strictly clinical in character, whilst the other is more strictly physiological. It is one thing for the medical man to ascertain what are the particular individual states, conditions of life, and occurrences, physical or moral, which have contributed to induce an attack of convulsions (to ascertain which he studies the 'predisposing' and 'exciting' causes of the disease); but it is quite a different problem when he endeavours to unravel, by anatomico-physiological data, the actual mode of production of the convulsions. In this latter part of the inquiry he has to do with what are called 'proximate' causes, and is brought face to face with a problem still involved in great obscurity, and concerning which the most opposite views are held by leading pathologists and physiologists. This second part of the problem of causation, for the present, concerns us less than the more strictly clinical side of the inquiry, and it will be only incidentally referred to in the present article. It will be fully considered in the article *EPILEPSY*.

Predisposing Causes.—The most important of these is the existence of an unduly excitable nervous system—one in which there is an exaltation of the tendency to produce reflex movements—an 'undue mobility of the nervous system,' as it is sometimes called. This is a state of things which is naturally more markedly in women than in men, and is also notably prominent in young children of both sexes. It is, moreover, much exaggerated in some children of nervous habit, who, besides being unduly emotional or excitable, are very prone to start or tremble on the least noise, and are subject to muscular twitchings in various parts of the body. With increasing age, and more especially in the male sex, we find the sensorial and emotional centres becoming less excitable, owing, in great part at least, to their more complete subordination to the controlling or inhibitive influence of the developing cerebral hemisphere.

The predisposing groundwork being of this nature, how is it caused, or to be accounted for?

(1). It may be inherited from one or both parents.

or from grandparents, who may themselves have possessed a nervous system of this type, and may, moreover, have been subject to fits or other well-marked disease of the nervous system. But though not inherited in the strict sense of the term it may (2) be innate; the patient may always (i.e. from birth) have possessed a nervous system of this type, as an accompaniment of the mere low vitality which is often seen in children born from parents who are simply weak and debilitated, or in those whose parents have been advanced in life. (3). At other times the nervous system may have acquired such predisposing characters some time during the life of the individual (especially during childhood or adolescence) owing to the action of various acts of conditions, some of the best established of which are these.—(a) The cachexia sometimes following measles, pertussis, &c.; (b) insufficient or improper food, (c) chronic diarrhoea, (d) hæmorrhages or exhausting discharges.

If we turn now to the various *exciting causes* we find these so powerfully influenced by the age of the patient, as to make it desirable to consider them in reference to different periods of life, which we may artificially though conveniently mark off from one another.

Infancy (from birth to end of 2nd year).—In certain cases convulsive attacks are congenital; and here perhaps the most frequent exciting cause is a meningeal effusion of blood which presses upon and irritates the surface of the brain—the extravasation having in some cases been occasioned during parturition where it has been prolonged or unnatural. These congenital attacks are most frequently associated either with more or less marked hemiplegia, or with a subsequent partial or distinct condition of imbecility or idiocy. Such unfortunate infants may continue quite unable to stand or even sit up; they remain unable to speak, and, as in a case which I have recently seen, the child may be quite blind. Meningeal or superficial hæmorrhages may also occur in young infants, under the strain of the mechanical congestion produced by violent fits of coughing in pertussis or bronchitis, and in some of these cases such effusion may be followed by convulsions. Fits in infancy may also follow falls or blows upon the head, though at this early age such occurrences are comparatively rare.

In infancy, again, convulsions may usher in or subsequently supervene in almost any acute disease, this being especially the case with measles, scarlet fever, and other of the exanthemata; in pneumonia or bronchitis; and also in tubercular meningitis.

But, still more frequently, convulsions in infancy are excited by mere peripheral irritations, as during the process of teething, from an overloaded stomach, or from indigestible food. Diarrhoea, worms, &c., also take their place as more or less frequent excitants of convulsive paroxysms in infants—though worms only begin to appear towards the end of this period. But though irritations in the field of distribution of the 5th and pneumogastric nerves are especially potent in exciting convulsions, irritations of other parts of the body may also lead to similar results, whether they are occasioned by the injudicious disposition of pins, by tight strings wounding or

irritating the skin of the body, or by any other means. The more distinctly predisposing conditions exist, the more frequently will any or all of these exciting causes give rise to an attack of convulsions.

Lastly, an infant which has taken the breast of a woman who has shortly before been much perturbed by violent anger, grief, or any other strong emotion, may thereafter, if predisposed, be seized with convulsions—probably owing to the milk of the nurse having been so altered in quality as to have led to gastric trouble and irritation in the infant.

Childhood (from the 2nd to the 13th year).—Most of those exciting causes which are influential during the last period continue to be occasionally operative in this—especially during the first half of it. Meningeal hæmorrhages are now rarer, though they may still occur during violent paroxysms of coughing, and also from falls or blows upon the head. The latter causes of hæmorrhage may, however, act in producing fits in other ways, e.g. by concussion, shock, &c., and they now come to be more frequently operative. The exanthemata are still apt to be preceded or associated with convulsive attacks; and irritations, especially from teething or irritants (undigested food or worms) in the intestinal canal, are also still apt to be followed by such a sequence.

During this period another cause of considerable potency comes into operation with great frequency, and this is fright. The first fit either follows the fright more or less immediately, or it may not take place for days—perhaps for weeks—after the sudden emotional disturbance. During the interval, however, the health and mental condition of the child is generally obviously disturbed. Proper treatment at this stage may prevent the occurrence of fits. Scrofulous tumours in the brain sometimes help to determine convulsions in children.

Adolescence (from the 13th to the 20th year).—Fright or other sudden emotions, falls upon or blows about the head, still appear as frequent exciters of convulsive attacks which recur (epilepsy) at this period of life, though meningeal hæmorrhages, acute diseases, and peripheral irritations are much less frequently operative than at earlier periods, since the special irritability of the nervous system characteristic of childhood decidedly abates as the cerebral hemispheres develop and begin to exercise a more powerfully controlling influence over the lower centres.

Other and new causes, however, come into play at this epoch. The establishment of puberty is a kind of crisis during which, independently of all other causes, convulsions or fits may be initiated in those whose nervous systems are at all predisposed towards such an occurrence. This is more especially so in the case of the female, partly because of the existence of a more frequent predisposition in persons of this sex, and partly because of extra excitations in association with the establishment of the catamenia—whether this be brought about imperfectly or in a natural manner. Ovarian or uterine irritation, or irregularity of the functions of these organs at any part of this period, may help to occasion fits which may or may not take an hysterical type. Masturbation may also be added as an occa-

sional provocative of epilepsy at this critical period of life, though I am inclined to think too much stress is often laid upon this as a cause. When operative this mode of excitation occurs more frequently with the male than with the female sex.

Excessive study and mental application, as well as worry or anxiety, must also undoubtedly be enumerated amongst the causes of epilepsy at this period of life.

Neither must we forget the possible existence of aneurysms of the arteries or of morbid growths in connection with some portion of the brain or its meninges, either of which may act as occasional excitants of epileptic paroxysms. This cause also figures in earlier periods of life—more especially in those of a scrofulous type. And in some of such cases the new-growth may lead to the supervention of chronic hydrocephalus, and thus render the occurrence of convulsions even still more likely.

Early Adult Age (20–40 years).—Fits originate much less frequently during this period of life than in adolescence or childhood. They are, however, apt to supervene more especially when the general health is lowered under the influence of various exciting causes. Grief and mental worry, more especially when combined with long-continued bad sleep, and the labours or cares of business, are then apt to induce them.

Blows or falls upon the head may still be followed by attacks of this kind, though perhaps with less frequency than in the earlier periods of life.

Syphilitic indurations or growths from the meninges may now occur; and other attacks (often of one-sided convulsion) may be determined by various pathological changes or accidents taking place in regions of the brain where more severe lesions would give rise to hemiplegia. The primary change in these cases may be minute hæmorrhages into the brain-substance, or minute and slight softening produced by stopping of small vessels (embolism or thrombosis). From lesions of this kind hemiplegia and epilepsy are often more or less associated. Occasionally the cause may be a non-syphilitic tumour, occupying the side or base of the brain.

Puerperal convulsions in the female, and uræmic convulsions in both sexes, are most frequently met with during this period of life. During pregnancy the reflex excitability of the nervous system is often greatly increased, and in the production of puerperal convulsions some amount of uræmia also intervenes not unfrequently. Intemperate habits, carried to excess, frequently produce fits, and so also may venereal excesses.

After Middle Age (40 years and onwards).—The mobility of the nervous system gradually diminishes during this period, so that epileptic attacks commence now with still less frequency. There is, however, one period (the climacteric) in the female sex in which this mobility is temporarily increased, and in which fits again become more frequent, under the influence of apparently slight exciting causes.

Although fits are only very rarely liable to be induced by the sequelæ of hæmorrhages or of softening of the brain, yet these events now

grow more common as age advances, and are therefore to an almost corresponding extent more liable to figure as causes of epileptic attacks. An attack of hæmorrhage or of softening may be ushered in by epileptiform convulsions (especially when the lesion occurs in certain parts of the brain), and in some cases such attacks may thereafter recur at irregular intervals. Exposure to great heat, or sunstroke, may also at this period, or earlier in life, act as the exciting cause of convulsions.

Mental overwork, worry, fright, and such-like influences, are much less likely to operate in persons over 40 than in earlier life; and the same is to be said of blows or injuries of the head, short of the most severe causing actual lesions of the brain. But the malnutrition and degeneration induced by intemperate habits may predispose to symptoms of this kind; and so also may blood-poisoning from renal disease, which is now not unfrequently present.

Various organic diseases of the brain, whether principally characterized by degenerations with a process of more or less general atrophy, or with localized overgrowth of connective tissue, are also not unfrequently productive of convulsions, either in persons of middle or of advanced age. A well-marked instance of the former of these associations is to be met with in general paralysis of the insane. Cysticerci on the surface of the brain have also in some recorded instances been the cause of most obstinately recurring convulsions.

Lastly, it should always be borne in mind that convulsions are sometimes the result of the action of poisons of various kinds upon persons of any age. Occasionally such poisoning may be brought about by articles of diet, such as mussels or fish in certain states, or from poisonous mushrooms; whilst at other times it results from some of the well-known narcotico-irritant poisons, taken either inadvertently or purposely.

ANATOMICAL CHARACTERS.—These may be said, so far as our present knowledge goes, to be absent. It is true that general or partial congestion of the brain may frequently be encountered in those who die during an attack of convulsions. But this congestion is to be regarded as a result rather than as a cause of the fit. The convulsions are due to mere molecular changes in the brain, inappreciable to, or at all events unappreciated as yet by, the most skilled microscopists. When fits occur in association with actual organic growths or other lesions of the cerebral cortex or elsewhere, such lesions may form merely the starting points for nervous impressions which travel downwards so as to upset the equilibrium of certain unstable or highly charged motor centres; just as a similar disturbance of nervous equilibrium with discharge of motor energy may result in another case from abnormal visceral impressions (induced it may be by indigestible matters in the intestine or by an acute disease of the lungs), or from some surface-irritation. In accordance with this point of view, such organic growths or other lesions need receive no further mention here. Those who may be inclined to think otherwise, should bear in mind the fact that convulsive attacks are easy to be produced in

animals from whom the cerebral hemispheres have been removed.

SYMPTOMS.—The varied nature of the causes make it impossible to say anything of moderate compass concerning the premonitory signs or symptoms which may precede an outbreak of convulsions. These must necessarily vary immensely in different cases. Some of the characters of the predisposing state have been already alluded to (p. 300). The onset is, however, often abrupt and without any distinct premonitory symptoms.

With regard to the actual characters of the attack it will be sufficient to say here that they also vary immensely in different cases; and as notwithstanding this great variability it is impossible in any individual case to tell, from the nature of a first convulsive fit, whether it will form a more or less isolated attack, or whether it will constitute one of a subsequently recurring series, the reader may, for this part of the subject, be referred to the description of the attacks given under *EPILEPSY*. All that is there said concerning the actual phenomena and mechanism of the attack, holds good for occasional convulsions as well as for those which are habitual. In each we have to do with (1) a more or less distinct stage of tonic spasms, followed (2) by one of clonic spasms, and (3) succeeded by a state of stupor. One or other of such stages is, however, not unfrequently more or less abortive. These attacks may, at times, so rapidly follow one another as to be merged into one long series or *status convulsivus*, differing in no respect from the analogous *status epilepticus*.

COMPLICATIONS AND SEQUELÆ.—The complications are most various, seeing that in different cases we may have to do with irritated gums, repletion, diarrhœa, worms, or an acute specific disease; whilst in other cases it may be with general debility and sleeplessness, with mental anxiety, puberty, or the climacteric period. Again pneumonia, renal disease, pregnancy, ovaritis, or some organic brain-disease may be the accompanying condition.

The nature of the sequelæ will depend principally upon the frequency of the attacks and the duration of the period during which the patient has been subject to the recurrence of them, so that for this part of the subject the reader may refer to the article *EPILEPSY*.

DIAGNOSIS.—There is very little difficulty in regard to the diagnosis of the affection. The differential characters of *Laryngismus Stridulus* are given elsewhere, and the absence of any real distinction between a fit of *Eclampsia* and a fit of *Epilepsy* has already been insisted upon. Neither of these affections can be easily confounded with certain forms of *Chorea*, which occasionally present themselves in adults, with movements not unlike those of ordinary convulsions. The more continuous nature of the movements, and the fact that consciousness is not impaired, suffices to distinguish all forms of *Chorea*. The spasms of *Tetanus* and *Hydrophobia* are also easily distinguishable from an ordinary attack of convulsions.

The characteristics of hysterical convulsions will be pointed out in the article on *HYSTERIA*.

The real difficulties from this point of view

of diagnosis have reference to the cause of the attack. To arrive at a decision in regard to this is often very difficult and occasionally impossible, at all events when a patient first comes under observation. At other times, however, the indications are so plain that there can be little or no difficulty. It is a question which should always be considered with the utmost care, since on the correctness of our conclusions in regard to this point the efficacy of the particular line of treatment which we adopt must necessarily depend. Nothing is more to be deprecated than hasty jumping at conclusions, from mere routine and superficial considerations. The condition of the patient must be carefully examined, and the nurse, attendants, or relatives must be closely questioned in order that we may learn as much as possible as to the previous state of health of the patient, and more especially as to the time and events which immediately preceded the first outbreak of an attack of convulsions. Examination and enquiries combined may convince us that the convulsions are (1) of the primary or idiopathic variety, immediately occasioned perhaps by fright, anxiety, overwork, overmuch or indigestible food, &c.; or we may come to the conclusion that the convulsions are (2) of the sympathetic order dependent upon pregnancy, renal disease, the onset of an acute specific fever or of pneumonia, or due to the existence of whooping cough, scarlet fever, &c. Or, in the absence of reasons for placing them in either of these categories, we may be forced to conclude that they are (3) symptomatic of some organic brain-disease, the nature of which must then be determined as nearly as possible, judging from the age of the patient, the mode of onset, his present state and associated conditions.

In any case we may have to enquire more closely as to hereditary tendencies, or acquired predisposing causes, which sometimes reduce the nervous system to such a degree of irritability as to lead to an attack of convulsions without the aid of any obvious exciting cause. In infants or very young children such a condition of the nervous system may display itself by great restlessness and startings at night, by the child's sleeping with half-open eyes, by drawing in of the thumbs across the palms, by twitchings of the limbs, of the angles of the mouth, or of the facial muscles generally. In older children and in young adults the signs which most easily mark a similar below-par condition of the nervous system are twitchings of the muscles about the angle of the mouth and of the tongue (the former being especially well seen when the latter organ is tremulously protruded for inspection) associated with debility, anorexia, partial insomnia, and general nervousness. In nervous girls fits are induced by very slight causes about the time when the catamenia become first established. The indications for treatment must in fact vary immensely in any five consecutive cases of convulsions to which the practitioner may be summoned.

Prognosis.—The possibilities under this head are at least six in number in regard to any case of convulsions:—(1) The patient may recover after having a single fit or a batch of them within a few hours or days, and may never have another

attack. (2) The patient may recover, and though he or she may not have fits habitually thereafter, they may recur at prolonged intervals, when predisposing circumstances chance to be strong or are supplemented by an exciting cause of unusual potency. Thus convulsions during teething may cease, and may not recur till the constitution has been lowered by some illness years after, or when the nervous system has been rendered more irritable, as at the time when the catamenia are about to commence, especially if some slight fright should also come into operation as an exciting cause. (3) The patient may recover, though he subsequently continues to have fits either at irregular or regular intervals; he becomes, in short, a confirmed epileptic. (4) The convulsions may come to be followed by temporary delirium or a more or less marked maniacal condition, recurring after all or some seizures. (5) The patient may recover from the convulsive attack and may or may not have another fit, though he may remain hemiplegic. (6) The patient may die during the attack or almost immediately afterwards, (a) from the effects of it, or (b) by reason of some organic lesion by which the fit itself has been determined.

Recoveries are fortunately common, but death, especially in infants, is by no means uncommon. We possess no accurate data to enable us to assign the numerical proportion of these terminations to one another and to the other above-mentioned sequences.

TREATMENT.—During the convulsion itself, whether we have to do with an infant or an adult, we must see that all clothes are thoroughly loose about the neck and chest, and the patient should be placed in the supine position with the head slightly raised. Beyond seeing that the patient does not knock or injure himself, owing to the violence of his movements, these should not be much restrained; although efforts should always be made to prevent the tongue being bitten, by slipping the most suitable thing at hand between the molar teeth on one side, when the age of the patient or the character of the fit renders it likely that this event might otherwise occur. Beyond such simple measures as this, the less we do during the actual continuance of the fit the better it will probably be for the patient. We know of no rational or successful means of cutting short an ordinary attack of convulsions, and in the face of such an attack we should be cautious lest evil might be done.

Where we have to do with a succession of attacks quickly following one another, and which have already lasted some time, the careful administration of chloroform may be tried, as it is very serviceable in many cases when a *status convulsivus* occurs in children or in adults—though it would not be desirable to have recourse to it in infants. Under similar circumstances, for the latter the warm bath may be substituted, and sometimes seems to do good. On the cessation of the convulsions, or during the intervals, the treatment to be adopted to prevent their recurrence must necessarily vary immensely according to the age of the patient, and according to the predisposing and exciting causes which appear to have been operative in inducing the attack.

An overloaded stomach will call for the speedy administration of an emetic, and where indigestible food has already passed into the intestine an emema or brisk purgative should be given. Diarrhoea must be checked, or anthelmintics administered when worms are suspected. Gums may be lanced if they seem really to need it. In many of these cases an acquired or hereditary predisposition will have to be combated by the careful regulation of the diet, so that nutritious and easily digested food are given in place of their opposites, whilst at the same time the most suitable nervine tonics and antispasmodics are administered. For general usefulness in such cases no remedies can compare with the bromides of potassium and ammonium. As part of the specific influence which they exercise over nervous tissue, they fortunately establish a tendency to quieter and sounder sleep, of which such patients often stand much in need. Ten grain doses three times a day should be given at the commencement to youths or adults, and afterwards increased if necessary. Or a larger dose may be given once a day, either in the morning or at night, according to the indications in each case. Quinine or belladonna may be often given simultaneously with great advantage. To young children or infants, the dose of the bromide must, of course, vary with their age. Valerianate of zinc and oxide of zinc are remedies of less power, though these and other drugs may be tried where bromides appear to fail. This general treatment is applicable to a large proportion of cases also in which in debilitated or 'nervous' patients fits have been brought on by fright, worry, or anxiety, or by no assignable cause. Fatigue of mind and body is always to be avoided, and in those instances in which over-attention to business or over-study have been in part operative in bringing on the fits, absolute rest must form an essential part of the treatment. In girls or young women in whom fits occur at the time of the establishment of the catamenia, or where they recur in association with an irregular menstrual function, the general health often requires our most careful attention.

The convulsions which belong to the class known as *sympathetic* have to be carefully considered in relation to the malady of which they are the forerunners or associates. When convulsions precede an attack of scarlet fever or of small-pox they usually subside of themselves as the disease develops. They are, however, of much more significance when occurring during the course or towards the close of one of these maladies or during an attack of whooping cough or of croup. Our indications for treatment must then be derived in the main from the general state of the patient, and this is also eminently the case where we have to do with uræmic convulsions.

The treatment of *symptomatic* convulsions, dependent upon actual organic brain-disease, must also necessarily be subordinated to that appropriate for the affection itself upon which such symptoms depend. No drug will be found more generally useful, however, than bromide of potassium in ten to fifteen-grain doses for an adult (administered three times a day), in checking or diminishing the repetition of convulsions in

these cases. Sometimes the action of the bromide seems to be favoured by combining it with moderate doses of digitalis, especially in those cases in which there is great general nervousness in association with a disordered cardiac rhythm. Where sounder sleep is urgently necessary, chloral, either alone or in combination with bromide of potassium, should be given at bed-time. Tinctures of sumbul or of henbane are also at times useful adjuvants. Where we have to do with tumours of the brain, and especially with syphilitic growths in the meninges, much better results are to be hoped for from large and increasing doses of iodide of potassium, either alone or in combination with small doses of bichloride of mercury, with the administration of nutritious food and attention to the improvement of the general health. See BRAIN; and SPINAL CORD, Diseases of. H. CHARLTON BASTIAN.

CO-ORDINATION.—This term is used in reference to muscular movements principally. Certain parts of the nervous system have more especially to do with the calling into activity, and therefore with combining, the contractions of different muscles, both simultaneously and in succession, in the precise order in which they occur in the several motor acts of which we are capable. The nervous arrangements upon which these actions depend have come into being, both in the race and in the individual, by processes of organic growth and development *pari passu* with the possibility of executing these several movements. It would be wrong to expect, therefore, that an isolated organ should exist solely for co-ordinating muscular movements. The execution of the most habitual of these must depend, to a large extent, upon the activity of the ordinary motor tracts of the spinal cord and brain. The extent or precise mode in which the cerebellum intervenes in certain higher forms of co-ordination is still involved in much obscurity. That it has some share in such functions may be regarded as certain, though it probably intervenes far less than some would have us believe, who regard the cerebellum as the organ for the co-ordination of muscular movements.

Many nervous affections exist in which the co-ordination of muscular movements is more or less impaired. One of the most familiar of these is locomotor ataxy, a disease dependent upon a morbid process in the posterior columns of the cord. Sclerosis of the antero-lateral columns of the cord also not unfrequently disturbs the execution of muscular movements, especially those of the upper extremities. Chorea gives rise to very similar uncertainties in the execution of muscular acts. Spasms of all kinds, in short, tend to interfere with the harmony of the muscular movements in the course of which they intervene. Stammering is an affection of this kind, implicating the muscles of articulation, and certain disturbed cardiac actions characterised by disordered rhythm can only be regarded as belonging to the same category.

The above-mentioned are common instances of impaired co-ordination of muscular movements dependent upon structural or functional changes in parts of the nervous system other than the cerebellum. Certain diseases of this

organ, however, are known to give rise to a distinct form of inco-ordination. It is characterised by a swaying, unsteady gait in walking, with legs straggling, and mostly wide apart, to which the term 'titubation' is commonly applied. Other kinds of inco-ordination may hereafter be proved to depend upon diseases of the cerebellum. These are still very imperfectly recognised, and this is especially true in regard to its merely functional perturbations.

Certain inco-ordinations in speech and writing are common. Instances are to be found in that use of wrong words or misapplication of terms which we meet with in aphasic and amnesic persons; also in the substitution of wrong words in the act of writing, or of wrong letters in the writing of words, when such substitution is mechanical and unintentional—when it is wholly distinct, therefore, from mere inability to spell. These defects are inco-ordinations of a complex kind, dependent upon the perturbed action of higher cerebral centres, in the same way that incoherent speech generally is dependent upon incoherent thought. There is reason to believe, indeed, that the same kind of ultimate defective nervous action which leads to inco-ordinations of movements when certain motor regions of the nervous system are affected, may, on the other hand, give rise to perverted perceptions (*illusions*) or to perverted thought (*incoherence*) when the disturbed nervous action occurs in other and in higher parts of the central nervous system.

H. CHARLTON BARTMAN.

COPHOSIS (κωφός, deaf).—Deafness. See HEARING, Disorders of.

COPPER, Poisoning by.—*Metallic copper* may be regarded as innocuous when swallowed, and the recent researches of Hirt show that those who are engaged in the metallurgy and manufacture of copper utensils are not specially liable to any diseases which can be attributed to copper as such. It is, indeed, stated that workers in copper enjoy an immunity from cholera, a conclusion which is based on very insufficient premises. It is contradicted by the occurrence of cholera among copper-smiths in Buscau in 1866, and by certain other cases of a like nature reported by Hirt. That the disease is seldom found among workers in copper is true, but that the copper has anything to do with this result is not proved.

Though pure copper may be regarded as innocuous, it is otherwise with *alloys of copper*, more particularly with the alloys of copper with zinc and tin, known under the names of brass and bronze respectively, and with compounds of copper with lead or arsenic. In these the injurious agent would appear to be the alloy, and not the copper itself. An affection of a febrile character, and known as 'brass-founder's ague,' occasionally occurs on fusing days, and is attributable to the zinc fumes which are generated by the melting process.

The *salts of copper*, on the other hand, are capable of causing injurious and fatal results. The more important salts, from a medico-legal point of view, are the sulphate, blue vitriol, or bluestone; the acetates (basic and neutral) constituting artificial verdigris; and the carbonate or natural verdigris. The manufacture of ver-

digris is carried on to a large extent in the south of France. Plates of copper are acted on by the skins of grapes which are allowed to undergo the acetous fermentation. Those engaged in this industry on the whole enjoy good health, and it is only rarely that symptoms can be directly traced to the work; and then only when through sheer carelessness and uncleanness quantities of the salt have been ingested. It is even said that dogs eat the refuse grape-skins without appearing to suffer from poisonous symptoms.

1. **Acute poisoning by copper.**—**SYMPTOMS.**—The salts of copper, when taken in sufficient quantity, cause symptoms of acute poisoning, frequently terminating fatally. Twelve to fifteen grains of the acetate have been sufficient to kill a dog within an hour. The fatal dose in man is not quite determined; but doses above the usual emetic dose of the sulphate (ten to fifteen grains) have caused serious symptoms, and death has resulted within four hours after swallowing some pieces of the sulphate. Half an ounce would probably cause a fatal result. The symptoms are essentially those of irritant poisoning, viz., styptic or coppery taste, constriction of the fauces, epigastric pain, violent vomiting and purging, followed by collapse and death, usually with tetanic or convulsive symptoms. That which characterises copper-poisoning more especially, as compared with other irritants, is the frequent occurrence of jaundice. In dogs copper usually causes death with symptoms of paralysis of the hinder extremities, in addition to the usual irritant symptoms. It is said also to have a paralytic action on the heart.

2. **Chronic poisoning by copper.**—It is generally stated that the long-continued introduction of copper into the system in small doses gives rise to a form of chronic poisoning known under the name of 'copper colic.'

SYMPTOMS.—The symptoms are essentially those of gastro-intestinal irritation, with nausea or sickness and diarrhoea. They have none of the characters of colic in the sense in which the term is usually employed. The hair and the cutaneous secretions of workers in copper and brass are sometimes found of a green colour, and a line is sometimes found at the margin of the gums and teeth, variously described by authors.—Corriean calling it purple, while Clapton calls it green.

Though symptoms of gastro-intestinal irritation, as above described, have been found among workers in copper, the question is whether they are in reality due to the copper, or merely symptoms of a not uncommon affection showing themselves among copper-workers. That copper does gain access into the system, and may be detected in the urine during life, and found in the bones after death, without the individual showing any manifest symptoms during life, seems pretty well established. But though we may regard it as certain that symptoms of copper-poisoning are more rarely found than those of lead-poisoning among those who have to deal with these metals, yet it would be a very unwarrantable conclusion, and contrary to all that we know of the action of poisons, to assert that a substance which is undoubtedly poisonous can be taken freely into the system with impunity.

This is a point of considerable interest in reference to the accidental or wilful adulteration of articles of food with copper salts. Many cases are on record of severe symptoms resulting from the use of copper utensils in cooking, or more frequently from the storage of water or articles of food in copper vessels, especially if the food contains oil—which, on turning rancid, dissolves the copper—or vegetable acids, or even large quantities of ordinary salt.

Copper salts are also employed intentionally to impart a green, fresh colour to pickles and preserved vegetables, such as peas. It is asserted that the quantity of copper necessary to produce this effect is infinitesimal, and that no poisonous effects can be proved to have resulted even from long-continued employment of these vegetables as articles of food. This is strongly maintained by M. Galippe, who has tried them on himself and family. Assuming the impossibility of proving the injurious effects of copper-tinted vegetables, the question comes to be principally a social and economic one, as to the propriety or legality of adulteration of food at all, and especially with a substance undoubtedly poisonous. Copper is said by some to be a natural constituent of the human body, but Bontigny furnishes strong grounds for attributing the minute quantity which may be found in the liver to accidental introduction into the system from cooking utensils, or from fruits raised on manure containing copper.

DIAGNOSIS.—The greenish or bluish colour of the vomited matters, which turn bright blue on the addition of ammonia, renders the diagnosis comparatively easy.

TREATMENT.—In acute cases the stomach should be evacuated by encouraging vomiting, or by the stomach-pump. Albumen in some form, as milk or white-of-egg, should be given in order to precipitate the copper. Iron filings may be given for a similar purpose.

In chronic poisoning the cause should be discovered and removed, or the individual removed from the cause. D. FRICKER.

CORN.—SYNON.: *clavus*; Fr. *Clou, cor*; Ger. *Leichdorn, die Hühnerauge*.

A corn is a thickening of the epidermis, caused by undue pressure and friction, as by boots, shoes, or implements of occupation. It is usually situated on a prominence, such as that of a joint, where the skin is subjected to double pressure, and is therefore unable to yield, or between the toes. Corns are most common on the feet.

A corn usually begins as a general and uniform thickening of the epidermis, which is termed a *callus*, (*tyloma, tyloma, Schwielen*). Callosities may occur on any part of the integument. Thus they may occupy the prominence of a joint, or spread over the heel or metatarsal cushion of the foot from pressure in walking, or occupy the metacarpal prominences of the hand as in boatmen.

The callusity is composed of laminated epidermis; is thickest in the centre, becoming thin towards the circumference; and is more or less hard and condensed, smooth and hornlike in appearance, and yellowish in colour. When the irritation which gives rise to a callusity is pro-

longed, effusion is apt to take place beneath it, and it is raised like a blister, the effused fluid being sometimes serous and sometimes sero-purulent. Whenever this happens, the subsequent separation of the horny layer results in spontaneous cure.

When the pressure giving rise to a callosity, instead of being diffused, is concentrated on a central point, the epidermis corresponding with that point increases in thickness, by its under surface, and forms a conical prominence; further pressure increases the length and breadth of the cone, and in this way a corn is established. Continued irritation enlarges the corn by hyperplasia of epidermic cells, and its pressure produces absorption of the derma, sometimes extending to the bone itself. Not unfrequently effusions of serum or blood take place beneath the conical prominence, and, in rare instances, a bursa is found between the corium and the joint.

At a late stage of its growth the corn has the appearance of a central core—technically, *the eye of the corn*—surrounded by a collar of smooth epidermis in the state of callosity. The core is a lamellated ovoid mass, corresponding in external figure with the cup by which it is produced; and consisting in substance of vertical cup-shaped lamellae closely packed one within the other. In an old corn the shape of the entire core is conical, the point resting on the sensitive skin, and the signification of the term *clou* or nail applied to it by the French is made manifest. The substance of the corn resembles horn both in colour and density, but between the toes, where moisture is generally present, it remains white and soft, like suddened cuticle, and is thence named *soft-corn*. Effusion at its base is more common in the soft than in the hard corn.

TREATMENT.—The treatment of a corn is to remove its cause, namely, pressure and friction; but when this is impracticable, to equalize pressure, by which the corn will revert to the state of callosity. The second indication is best effected by some simple unirritating application, such as soap or lead-plaster spread on wash-leather. As a preliminary to this application, as much of the hard epidermis as possible should be removed by soaking and scraping, and the core turned out with a blunt-pointed instrument. The soft corn may be removed as the hard one, or by snipping with scissors. When there is much pain and inflammation about the corn it should be treated by means of water-dressing. Chronic corns and callosities are much benefited by painting with iodine liniment, and the use of an unirritating protective plaster.

ERASMUS WILSON.

CORNEITIS.—Inflammation of the cornea. See EYE AND ITS APPENDAGES, DISEASES OF.

CORNUA (*cornu*, a horn).—A synonym for horns. See HORNS.

CORONARY ARTERIES, Diseases of. The diseases of the coronary arteries may be classified as follows: (a) atheroma and calcification; (b) aneurism; (c) occlusion of the orifice; (d) thrombosis; and (e) syphilitic disease.

a. Atheroma and calcification of the coronary arteries are ordinary, but by no means con-

stant sequelæ of similar changes in the root of the aorta. The disease may be general, affecting both vessels equally or unequally; or it may be limited to one of them, or even to a primary branch of either; and may lead to fatty degeneration or fibroid change of the corresponding substance of the heart. The experiments of Mr. Erichsen and M. Schiff have proved that the nutrition of the heart in health depends upon a free coronary circulation, and pathology has confirmed this conclusion. Dr. Quain found the coronary arteries diseased or obstructed in 13 out of 33 cases of fatty degeneration of the heart, and in one of these cases, the trunks of both vessels being healthy, a calcified coronary branch led to the only portion of the heart exhibiting fatty change. Of 55 cases of fatty degeneration of the heart collated by the author from the *Transactions* of the London Pathological Society, 21 exhibited atheromatous or calcific change of the coronary arteries. In 10 of these death occurred by rupture of the left ventricle, in 1 by rupture of the right ventricle, and in 2 by rupture of the septum ventriculorum, the coronary branch leading to the seat of rupture having been, in every instance, in a more advanced state of disease than the other portions of the vessel. From the foregoing statistics it would appear, that whilst fatty degeneration of the heart may exist independently of disease of the coronary arteries, the latter condition may be regarded as the *immediate* cause of fatty change in the heart, in the proportion of about 38 per cent. of all cases.

SYMPTOMS AND SIGNS.—There are none which are peculiar to this disease; those which exist being due to the consecutive changes in the substance of the heart. The doctrine formerly held, that calcification of the coronary arteries was the cause of angina pectoris, is no longer tenable. In an example of this disease in its most typical form, eventuating in death, which recently came under the writer's notice, the coronary arteries were found, on examination, to be perfectly sound.

b. Aneurism of the coronary arteries is of rare occurrence. It is usually preceded by atheromatous or calcific changes in the coats of the vessels, and may, therefore, be regarded as a disease of middle or advanced age. Dr. Gee has, however, published an example of coronary aneurism in which the patient was a boy of only seven years.

SYMPTOMS AND SIGNS.—There is no positive indication of coronary aneurism during life. When the termination is fatal, as it usually is, death occurs by hæmorrhage into the pericardium from rupture of the sac.

c. Occlusion of the orifices of the coronary arteries has been met with only in connection with calcific changes in the root of the aorta, a partially detached calcareous plate overlying the orifice of either vessel (both are rarely affected), and partially or completely shutting off the circulation. There are no *symptoms* distinct from those of the principal disease.

d. Thrombosis of the coronary arteries is a frequent result of disease in the coats of these vessels; and, owing to their small size, complete blocking and arrest of circulation through them

are the ordinary consequences of this accident. The heart-substance, depending upon the occluded vessel for its vascular supply, quickly undergoes the atrophic changes of fibroid or fatty degeneration. Special *symptoms* are entirely wanting.

Disease or obstruction of the coronary arteries, with the ordinary consequences—fatty degeneration of the heart, and anæmia with white softening of the brain—are the conditions usually found in cases of permanently slow pulse.

e. Syphilitic disease of the coronary arteries has been recorded in a few instances, but its identification depended entirely upon the history and the concomitant symptoms, the deposit being histologically indistinguishable from ordinary atheroma.

THOMAS HAYDEN.

CORPORA AMYLACEA (*corpus*, a body; and *amylum*, starch).—These minute bodies, which were described in this country by Dr. Quain and Dr. Hughes Bennett in the 2nd and 3rd vols. of the *Transactions* of the Pathological Society, were thus named by Virchow. They are generally only visible with the aid of the microscope, but sometimes are large enough to be seen by the naked eye, and now and then attain some size. Usually they are round or oval, and present a concentric, laminated arrangement, which is made more apparent by the action of acetic acid. They often have a yellowish tinge. In appearance corpora amylacea somewhat resemble starch-granules, and they are tinged brown or bluish by the action of iodine upon them. These bodies were formerly supposed to be composed of starch, and hence their name. This is not the case, however, and their actual chemical composition is not clearly known; it probably differs in different structures. Bodies resembling corpora amylacea in appearance and arrangement have been found in various parts, but they have attracted most attention in connexion with the nerve-centres, being particularly observed when these are the seat of atrophy or degeneration; they are also seen in the choroid plexus.

FREDERICK T. ROBERTS.

CORPORA QUADRIGEMINA, Lesions of.—The facts of comparative anatomy and experimental physiology tend to show that the corpora quadrigemina (*corpora bigemina* or *optic lobes* of the lower vertebrates) are in relation not only with vision and irido-motor co-ordination, but also with those functions which are, to a large extent, independent of the cerebral hemispheres, viz., equilibration and locomotor co-ordination.

The facts of human pathology, though not opposed to these data, cannot be made the basis of very precise conclusions as to the diagnostic indications of disease of these ganglia, as it is exceedingly rare to find disease limited to this region anatomically or functionally.

The corpora quadrigemina are, however, not unfrequently involved in lesions which involve neighbouring parts, such as meningitis—simple and tubercular, tumours, especially of the pineal gland and middle lobe of the cerebellum, &c.; but disease strictly limited to the corpora quadrigemina, such as local softening, is extremely rare, and hæmorrhage is unknown.

It is a fact agreed on by all experimenters that when the anterior tubercles, which are more especially connected with the optic tracts, are destroyed, vision is abolished, and that if the lesion is unilateral, the blindness occurs on the side opposite the lesion.

These phenomena in animals are in accordance with what has been observed in man. Dr. Bastian has recorded a case of total blindness, in which the cause proved to be softening limited to the anterior tubercles of the corpora quadrigemina (*Paralysis from Brain Disease*, p. 115).

It has been found experimentally in animals, and also in man, that atrophy of the opposite tubercle ensues when the eye has been destroyed. Irido-motor action is also paralysed by destruction of the corpora quadrigemina, a result which, however, is stated not to occur unless the injury is more than superficial and implicates the oculo-motor nuclei.

Disturbances of equilibration and co-ordination also result from lesion of the corpora quadrigemina. These are attributed to lesion of the subjacent tracts, and, according to Luasana and Lemoigne, more particularly to lesion of the subjacent superior cerebellar peduncle. For his own part, the writer thinks that all attempts at differentiation are pure hypotheses, and from the nature of the question must remain so. But, from whatever cause, there is no doubt that the disturbances alluded to do occur.

Irritation of the corpora quadrigemina on one side causes dilatation of the pupils and a hemi-ophthalmos of the opposite side, which becomes general if the irritation is prolonged or bilateral, the head being retracted and the legs extended, trismus also being very marked. According to Luasana and Lemoigne unilateral lesion of the corpora quadrigemina causes an incurvation of the trunk and gyration to the side of lesion. This would agree with the effects of irritation, being naturally a reversal of the phenomena. Clinical illustrations of these facts in the lower animals are difficult to find, for the reasons above mentioned, but a case reported by Dr. Duffin (*Chin. Soc. Trans.*, vol. ix., p. 187) which the writer had an opportunity of seeing and examining *post mortem*, is important in this relation. This was a case of tumour of the pineal gland, which, besides passing forward into the third ventricle, pushed underneath the aqueduct of Sylvius, stretching and causing atrophy of the corpora quadrigemina. The symptoms, in addition to those of cerebral tumour, viz., violent occipital headache and double optic neuritis, were double vision followed by loss of sight, vertigo, specially marked when the eyes were open, staggering gait, and tendency to retraction of the head and rigidity of the dorsal muscles. The pupils were large and sluggish. These symptoms, to a certain extent, resemble those caused by tumour in the middle lobe of the cerebellum, and it is a question how far these latter may be due to mechanical irritation of these ganglia. But we may infer that such a combination of symptoms as the above points to lesion of the corpora quadrigemina, or of the middle lobe of the cerebellum, though we cannot be certain of absolute limitation of the lesion.

Naturally the same secondary affection of the

functions of the cerebral hemispheres occurs from tumours situated in this region, as in cases of tumours of the middle cerebellar lobe.

Pressure on the veins of Galen leads to dropsy of the cerebral ventricles, and its consequences on the cerebral circulation and functions.

D. FERRIER.
